170 VARICK STREET
NEW YORK, N. Y.

William Turner, in 1886, wrote "with the exception of the skull no portion of the skeleton presents greater individual variations than the pelvis". Vesalius' drawing of the pelvis showed the sacrum to consist of six segments. Oddly, the writings of Deventer published in 1725, also describes the sacrum as consisting of six segments.

SPRAGUE, E. W., SCHAAF, R. A., MACARTHUR, C., HAWKES, S. Z., HAUTMAN, H., AND HALEY, P. W.

A Study of Appendicitis. S. G. O., Vol. 66, No. 2, pp. 166-172. Feb. 1, 1938.

The authors present a review of

1463 consecutive cases of acute appendicitis, all of which were operated upon. The technique was practically the same in all cases; the appendix being crushed, ligated, then severed with a cautery and inverted by means of a purse string suture. A row of Czerny-Lembert sutures is used to cover this and the raw edges of the meso-appendix. The appendix was not removed in three cases, which were complicated by general peritonitis. In septic cases great care is exercised to protect the healthy peritoneum. Abscesses are drained without entering the general peritoneal cavity if possible. The history of chills or the presence of a remittent type of fever

curve was taken to indicate the presence of the thrombophlebitis of some extent.

The authors have not used the so-called expectant treatment in any of these cases because they feel unable to judge which cases may localize safely and which ones may extend and continue to spread.

The conclusion is apparent from this study that operation is comparatively safe during the first 18 hours after onset. After that time the danger rises in direct proportion to the time elapsing between the onset and the time of operation. The mortality in this series of cases is 2.73 per cent.

Ten tables accompany the article.

GAUNT, WILLIAM E., IRVING, JAMES T. AND THOMPSON, WILLIAM.

Calcium and Phosphorus Deficiencies in a Poor Human Dietary. British Med. Jour., 770-773, April 9, 1938.

Experiments are cited in which it was shown that the nutritional value of a poor human dietary can be greatly improved by the addition of milk, and green food supplements. Experiments reported here demonstrate that in rats bred from stock this improvement is due largely to the calcium and phosphorus contained in the supplements. This conclusion is based upon a comparison of the rate of the growth, calcification of bones and teeth, and reproductive performance in various groups of rats, all bred from stock.

VAUGHAN, WARREN T.

Food Idiosyncrasy as a Factor of Importance in Gastro-enterology and in Allergy. The Review of Gastroenterology, March, 1938.

The first reference in all literature which might be taken as pertinent to the subject of food idiosyncrasy was the statement of Lucretius, a Roman—"One man's food may be highly poisonous to another," since corrupted into "One man's meat is another man's poison." Allergy and idiosyncrasy mean precisely the same thing today, although perhaps the term "sensitive" in connection with foods might be considered more general. Wolff-Eisner's suggestion in 1906 that hay fever might be an allergic disease first showed that there might be a connection between experimental anaphylaxis and spontaneous clinical disease, but it was not until 1910 that Doerr suggested a common basis for food idiosyncrasy and anaphylaxis. The first book on clinical allergy, by Minet and LeClercq in 1913, devoted only nine pages to food allergy and concluded that the phenomenon must be quite rare. Schloss in America in

The most convenient and pleasant method of administering Gastric Hydrochloric Acid

GLUTAN H-C-L

Indications. The literature shows GLUTAN H-C-L (Glutamic Acid Hydrochloride) to be a superior source of free hydrochloric acid in the treatment of gastric achlorhydria, hypochlorhydria, nervous anorexia, and in secondary anemias requiring a high protein diet, or whenever it is necessary to supplement or replace gastric hydrochloric acid.

Advantages. GLUTAN H-C-L is replacing the old methods of administering hydrochloric acid because—

No unpleasant taste.

No sipping through a glass tube.

No irritation of the esophagus or decalcification of the teeth.

Put up in capsules which may be carried in purse, handbag or pocket—patients appreciate this convenience factor.

Contains glutamic acid, a centuries old condiment—acting with hydrochloric acid the two produce a sense of well being after eating that is novel to patients who have long suffered from anorexia due to hypochlorhydria.

Supplied. GLUTAN H-C-L is put up in capsules, each of which is approximately equivalent to 10 minims of diluted hydrochloric acid U.S.P.

Bottles of 100, 500, and 1000 capsules.

Fill in and mail the attached coupon for a clinical sample and descriptive literature.

1 tablespoon...	60 cal.

Concentrated feeding is indicated in certain digestive and nutritional disturbances. The quantity of feeding given at one time is reduced and the caloric intake maintained by concentrated mixtures. Karo added to dried or evaporated milk is particularly adapted for concentrated feedings.

But other articles of diet can be enriched with calories—Karo provides 60 calories per tablespoon. It is relished added to milk, fruit, vegetables, cereals, breads, desserts. Karo is a concentrated carbohydrate that makes food more palatable.

Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

FREE to Physicians only:

Convenient Calculator of Infant Feeding Formulas; accurate, instructive, helpful. On receipt of Physician's prescription blank, giving name and address, the Calculator will be forwarded. Write Corn Products Sales Co., Dept. D^{N-8}, 17 Battery Place, New York, N. Y.

1912 applied skin tests and showed that, while explosive instances of food allergy were not common, that a wide variety of milder symptoms could be attributed to the same cause. Allergic symptoms referable to the digestive tract may result from food or drugs. The two commonest manifestations in the lips and mouth are angioneurotic edema and stomatitis following the ingestion of foods or drugs or the use of dental powders, pastes, mouth washes or even chewing gum. The recurrent form of herpes labialis is not infrequently associated with food allergy, and the same applies to many cases of recurrent canker sores in the

mouth. The classical allergic reaction in the stomach is associated with nausea and vomiting soon after the ingestion of the allergic excitant: if the latter is not vomited, the colon may later react with diarrhea and even true mucous colitis. Even perianal eczema may be due to food allergy and it seems that about one-third of cases of pruritis ani and perianal eczema, which are not due to pathologic conditions in the rectum can be relieved by a carefully studied plan of food avoidances. It is probably true that at times symptoms of gall bladder disease are due not to gall bladder infection but to the

effects on the gall bladder of food allergy, for it has been shown that in a sensitized animal, the local chemical irritation of a tissue may result in the accumulation of antigen at the point irritated; and it is recognized that the empirically-discovered gall bladder diets usually eliminated such definitely allergy-producing foods as strawberries and sea foods. Thus allergy may become a local complication superimposed upon the basis of an infected gall bladder. For the same reason, some cases of peptic ulcer have superimposed upon the ulcer a definite tendency to local allergic reaction, and in such cases the avoidance of the allergy-inducing food (notably milk) may result in symptomatic improvement very promptly. At times the symptoms of appendicitis may be imitated by food allergy. Some patients with characteristic history of chronic appendicitis, but who did not improve after operation, were found to have marked eosinophilic infiltration of their amputated appendices, and it was considered that this "appendiceal allergy" was but a part of an allergic colitis. The Walzer reaction suggested that possibly proteins are often absorbed from the digestive tract in a sufficiently unaltered state to be antigenic after absorption, but the further work of Thiers and Chevallier indicated that even after gastric digestion and after removal of protein by ultra-filtration food could still be allergy-producing. Possibly the active factor is not the protein but an associated hapten. The leukopenic index is more reliable than the skin tests in determining allergic substances in individual cases, but both ought to be used. The elimination diets of Rowe or the food diary of Vaughan are useful in detecting the offending food in many obscure cases. At the lowest estimate ten per cent of the population of the United States is frankly allergic, and for that reason it becomes evident that allergy must play a considerable part in the study of gastro-intestinal symptomatology.

LEVINE, A. L. AND SHUSHAN, MORRIS.
The Value of the Medical Plan of Treatment in Intestinal Obstruction. The Review of Gastro-enterology, March, 1938.

A middle position may be discovered between those who believe that intestinal obstruction is invariably a surgical emergency and those who do not, and careful study, undertaken for the purpose of creating distinctions may persuade medical nihilists that medical treatment has a definite place, not only because many cases ought to be operated upon only as a last resort but because medical treatment forms a vital pre- and post-operative requirement, none too well

Zymenol

Yeast Enzymes in Oil Emulsion

INDICATED FOR SUMMER DIARRHEA (Intestinal Flu---Summer Colitis) CONTROL

Without constipating after effect.

Both putrefaction and excessive fermentation in the intestinal tract are checked by the catalytic action of Zymenol. Brewers Yeast Enzymes (without living, complete cells). Fecal mass becomes soft and bulky, less toxic and less irritating. Normal evacuation is restored by natural impulse without drugs, roughage, artificial bulk or agents preferably avoided. (No Phenolphthalein. No Cascara. No Purgative).

The more normal physiological action of Zymenol is demonstrated by its effectiveness in the stagnant as well as the irritable, unstable bowel.

Sugar-free, Ideal for Diabetics.

No Leakage. Less Expensive.

Well tolerated by all ages.

BASIC OPERATIONS IN COMMERCIAL CANNING PROCEDURES

VI. COOLING THE TIN CONTAINER AFTER THERMAL PROCESSING

● On this page we have previously described certain basic operations in commercial canning procedures. These have included cleansing of the raw material; blanching; exhausting or pre-heating; sealing the tin container; and thermal processing of the sealed container. In this—the last of this series—we shall discuss the final basic operation, namely, the cooling of the sealed can immediately after the heat process.

One main reason for rapid and thorough cooling of the can contents—as soon as the objective of the heat treatment has been fulfilled—is more or less self-evident. Prompt cooling checks the action of the heat and thus prevents undue softening in texture or change in color of the food. Also important, particularly in the case of foods of an acid nature, is the prevention of excessive chemical action between the food and the metal container, which may occur if the contents of the can remain hot for an extended period of time. In modern practice, two types of cooling are commonly used, namely, air cooling and water cooling.

Air cooling, as the name implies, involves cooling of the tin container by facilitating radiation of its heat into the air. This type of cooling is adaptable to certain products in small cans. In other products, or in the case of larger cans, it is employed chiefly when the slower loss of heat, characteristic of this cooling method, is essential either for preservation of the food, or for the production of certain quality characteristics in the final product. Modern air cooling is accomplished in well ventilated, specially designed warehouses where the cans are piled in rows, allowing ample space between rows for efficient air circulation.

The several methods of water cooling and the technique by which they are carried out are detailed elsewhere (1). Briefly, water cooling may be effected in a variety of ways. The hot cans may be cooled by admitting water into the retort in which they were processed, or they may be cooled after removal from the retort by conveying the cans through tanks of cold, running water or through cold water showers. Large size, or irregularly shaped cans—processed under steam pressure—must be cooled in the closed retort at the end of the process to avoid undue strain on the containers. This is accomplished by “pressure cooling” in which pressure is maintained in the retort during the cooling of the cans, to counterbalance the pressure which develops during the process within the can itself. Commercially, cans are water-cooled to about 100°F. so that enough residual heat remains to dry the can exterior.

Present day canners are fully aware of the importance of cooling their products rapidly and completely as soon as the process is completed, in order to insure the production of canned foods with high quality characteristics. Consequently, in modern canneries the cooling operations are strictly supervised like the other basic operations in the commercial canning procedure. After inspection and labeling, the cooled cans are then ready to enter distribution channels for delivery to the consumer.

In this series of six discussions, we have attempted not only to describe the basic steps in commercial canning procedures, but also to explain their purposes. We trust this series may help bring a better understanding of this important method of food preservation.

MEAD JOHNSON & COMPANY

Evansville, Ind.

U. S. A.

recognized at the present time. Since obstruction is at times due to fecoliths and encrusted gall stones attempting passage through the bowel, operation ought to be delayed until the colon can be flushed out and the stomach and duodenum drained by catheter in a double effort to relieve obstruction and intoxication, because so frequently operation results in death from surgical shock even though the cause of the obstruction be very simple. Whether the cause be obstruction, paralysis or reflex ileus, the symptoms depend largely on the position of the block, high blockage being the most dangerous and rapid in development, and resulting in a quick dehydration and chloride deprivation. Frequent lavage of the stomach via the nasal catheter, the introduction of fluids and dilute HCl through this catheter at intervals, oil enemas, interstitial injection of 2,000 cc. of glucose in saline each 24 hours, the heat tent over the abdomen, cardiac stimulants and morphine for rest are suggested, both pre-operatively and postoperatively. Complete cooperation between surgeon and gastro-enterologist spells a high measure of success.

DE RIVAS, DAMASO.

The Rational Treatment of Amebic Dysentery with Special Reference to the Eradication of the Parasite by the Intra-colonic Thermic Method. The Review of Gastro-enterology, March, 1938.

The author uses colonic instillations of a 1-5000 copper sulphate in saline solution with glycerine and laudanum added, keeping the temperature very close to 45 to 47 degrees C. It is a procedure which is non-effective or even dangerous in inexperienced hands and depends for its efficacy upon the critical death point of *Endameba histolytica*. He relies upon the sufficiently frequent use of this method more securely than upon the use of any drug, and checks the progress by the presence of amebae or cysts or occult blood in the stools. and the healing of the ulcers, but not by the presence or absence of symptoms. He quotes Smithies as support in the idea of ceasing to rely upon many expensive drugs with claimed specificity of action, and compares Amebiasis to syphilis, in that both diseases are more efficiently cured by prolonged careful application of simple and known remedies than by the erratic use of new and much vaunted ones.

HARTZELL, J. B.

The Treatment of Fistulas of the Small Intestine. S. G. O., Vol. 66, No. 1, pp. 103-116, Jan., 1938.

The author discusses the treatment of small fistulas by means of pastes, buttons, discs and other devices and presents his modification of the rubber

DUOCHOL
(PLESSNER)

in Chronic Cholecystitis Toxic Hepatitis Stone-Free Cholangitis

Duochol (Plessner) provides the specific pharmacologic influence needed in many affections of the biliary passages. Containing highly purified bile salts and sodium salicylate (2 gr. of each), it intensifies bile secretion by the liver and increases cholecystic evacuation. Drainage of the bile ducts and gallbladder is thus encouraged, leading to rapid subjective and objective improvement in chronic cholecystitis, toxic hepatitis, and stone-free cholangitis.

Samples and literature sent

disc. The efferent and afferent limbs of the fistula are probed and a wax model of the interior of the bowel is made. This is long enough to extend well into healthy bowel. This model is then cast in pliable rubber, which is inserted into the limbs of the fistula. Into the exposed portion of this rubber mold a heavy silk suture is placed. If necessary two sutures are inserted at different points in the mold and fastened to a crossbar on the surface of the abdomen. As the fistula heals a smaller rubber mold is made and inserted. Finally after the fistula is completely healed the sutures may be cut and removed and the mold will pass through the intestinal tract.

Prerequisite to the success of this method is the complete absence of any degree of intestinal obstruction below the fistulous opening.

Eighteen figures from case reports and a bibliography accompany the article.

Nelson M. Percy, Chicago.

HAWKES, STUART Z.

Thrombophlebitis of the Appendiceal Vein Complicating Acute Appendicitis. S. G. O., Vol. 66, No. 1, pp. 62-78, Jan., 1938.

Thrombophlebitis of the appendiceal vein occurs when the infection tends to spread through the tissues. This thrombus serves to stop the spread of infection, but if the infection is so virulent as to cause enlargement of the thrombus and extension of it proximally in the appendiceal vein small emboli may break off and lodge in the liver. Such a happening is usually denoted by the occurrence of a chill and a sharp rise in the patient's temperature. This is frequently the beginning of a liver abscess and marks that case of appendicitis as one with a more grave outlook. If the thrombus has extended beyond the appendiceal vein and is giving off small emboli from a point in the ileo-colic vein it should be excised or ligated at the time the appendix is removed. If simple appendectomy without excision or ligation of the thrombosed vein is performed the patient will continue to have chills post-operatively and the possibility of the development of a liver abscess becomes much greater.

The author describes the course of the appendiceal and the ileo-colic vein and points out that the ligature should be placed at a point distal to the juncture of that vein with the right colic vein.

Early recognition and proper treatment of this type of appendicitis the author believes may contribute to lowering the mortality rate of appendicitis as a whole.

Three figures and a summary of eight cases accompany the article.

Nelson M. Percy, Chicago.

BERMAN, J. K.

Congenital Anomalies of the Rectum and Anus. S. G. O., Vol. 66, No. 1, pp. 11-22, Jan., 1938.

Congenital anomalies of the rectum and anus are rare. Their diagnosis presents no difficulty but recognition of the type of anomaly present requires a complete knowledge of the embryological development of the mesenteron and proctodeum.

Anomalies of the anus arise from maldevelopment of the proctodeum, while those of the rectum result from maldevelopment of the mesenteron. An accurate anatomical classification as proposed by Fraser, follows:

1. Congenital narrowing of the anal canal.
2. Congenital occlusion of the anal canal.
3. Abnormal location of the anus.
4. Congenital absence of the anus.
5. Total absence of the rectum.
6. Atresia of the lower end of the rectum.
7. Membranous occlusion of the rectum.
8. Recto-vaginal, recto-urethral and recto-vesical fistulas.

The symptoms are those of complete or partial intestinal obstruction with distension of the abdomen. In the fistulous types the parents will have noted that there is an abnormal opening with an absence of the normal anus.

The diagnosis is difficult. X-ray examinations with the baby held in an upside down position will reveal the position of the blind gut if it contains gas. Gas is rarely present beyond the hepatic flexure during the first 24 hours of life. Fluoroscopy with massage of gas into the blind gut is a valuable method. Injections of 12½ per cent sodium Iodide into an external fistula will reveal the course of an internal fistula if one is present. Colostomy and digital exploration of the blind gut is dangerous.

Treatment depends on the type of anomaly present and the accuracy of diagnosis. Colostomy should be avoided if possible. Dissections should be made from below through a longitudinal incision from the perineal body to the tip of the coccyx. This will be through the sphincter muscle which develops independently in the regional mesenchyma. Local anesthesia should be used as the straining and crying of the baby tends to push the blind gut down in the desired position. If a fistula is present it should be left alone until the child is older. The author uses No. 0 catgut to suture the mucosa of the bowel to the skin.

A brief summary of 23 cases of congenital anomaly of the rectum and anus with eleven figures and two tables accompany the article.

Nelson M. Percy, Chicago.

SUMMER FATIGUE

from Tissue Drought and Mineral Depletion

Excessive summer perspiration drains both fluid and essential minerals from body tissues. Inadequate replenishment may lead to fatigue, headache, lassitude, dermatoses, and other symptoms of dehydration.

Sal Hepatica—a half to a full teaspoonful in a glass of water once or twice daily—aids nature in overcoming this tissue drought and

mineral depletion. The effect and taste of famous natural mineral spring waters are simulated—efficiently and most economically. In this dosage the laxative action is slight. Of course, the usual dosage of Sal Hepatica affords dependable laxation. The intestines are cleansed of waste gently and effectively. ●

MULHOLLAND, H. B.

Intravenous Liver Extract in the Therapy of Pernicious Anemia: Report of a Case. Ann. Int. Med., Vol. 11, No. 4, p. 671, Oct., 1937.

The author states that some cases of pernicious anemia will not respond to liver or liver extract and ventriculin when given orally but will respond to intramuscular injections of liver extract. The author cites a very comprehensive case history, over a period of eighteen months, in which oral administration of liver extract was efficient for a period, then failed; intramuscular injections reacted similarly and was then followed by five intravenous injections of 20 c.c. of specially prepared liver extract, with less reaction to each successive dose and causing such improvement that the patient was able to leave the hospital for his home. Since then he has used one intramuscular injection of liver extract each week. Over a stay of 120 days in the hospital both the blood picture and general health were much improved.

In his comments Dr. Mulholland reviews the literature of other authors in which liver extract was administered intravenously.

B. E. Vincent Lyon and C. H. Aronld.

VAUGHAN, JANET M.

Anemia and the Gastro-intestinal Tract. British Med. Jour., 57-59, July 9, 1938.

It is recognized today that the commonest cause of anemia is a lack of one or other of the essential hemopoietic principles. The known hemopoietic principles are iron, the P.A. substance in liver effective in Addisonian pernicious anemia, and vitamin C. Minute quantities of such minerals as copper, cobalt, and manganese may be

required but are usually present in adequate amounts even in the poorest diets.

An adequate supply of hemopoietic principles may be rendered inadequate due to certain disturbances of the gastro-intestinal tract such as, hemorrhage, deficiency of gastric digestion, deficiency of intestinal absorption, and production of toxic substances.

The commonest sources of gastro-intestinal hemorrhage are bleeding gastric and duodenal ulcers and hemorrhoids. In all cases of anemia of unknown etiology an analysis of the stools for occult blood is an essential investigation.

Deficiency of gastric digestion may be due to organic lesions, diminished secretion of hydrochloric acid, or diminished secretion of the intrinsic factor of Castle.

By organic lesions of the stomach are meant new growths and complete or partial gastric resection. The anemia in such cases is due in part to the diminished gastric secretion and in part to altered intestinal function. It usually responds well to treatment with iron and liver extract.

There is a high incidence of achlorhydria associated with all types of anemia, but the exact etiological relationship of gastric acid secretion to anemia has not been established because of conflicting evidence in the literature.

Some cases of Addisonian pernicious anemia also show an iron deficiency. In such cases large doses of iron must be given along with the liver extract to secure a satisfactory hemotological response. This point should be remembered in order to combat the onset or further development of subacute combined degeneration of the cord.

Deficiency of intestinal absorption may be due to changes in pH, increased motility, abnormalities of muscle tone, or abnormalities of the mucosa. The anemia seen in such conditions is often of a mixed type—that is, there is a deficiency of both the iron and the P.A. principle.

For HYPERACIDITY and the medical management of PEPTIC ULCER

COLLOIDAL
ALUMINUM
HYDROXIDE
(TRUESDALE)

THE etiologic role of excess gastric acidity in the development of peptic ulcer renders its control imperative in cases where ulceration is feared or has already progressed.

Colloidal Aluminum Hydroxide (Truesdale) provides a safe, efficient agent . . . as a help in the prevention of ulceration, or as a positive stimulus to the healing process. Prepared by special process, it is rigidly standardized to contain 4% to 5% of alumi-

num hydroxide with approximately 0.5% sodium chloride. By direct titration, using Toepfer's reagent, it can adsorb and neutralize more than 10 times its volume of N/10 hydrochloric acid in 10 minutes; and more than 12 times its volume in 30 minutes.

Thus it prevents unbuffered gastric juice from coming into contact with the ulcer itself, and by its unusual astringent and demulcent properties, helps to control hematemesis, and provide immediate mechanical protection against irritation. Important for the relief of pain is its efficacy in reducing hyperperistalsis and pylorospasm.

No deleterious effects follow its ingestion. It does not disturb the acid-base balance, nor cause evolution of gas, nor stimulate a secondary acid rise.

By oral administration, ambulatory cases may be successfully relieved.

By continuous drip administration, severe cases yield the largest percentage of cures in the shortest period of time.

Achieve

NORMAL BOWEL EVACUATION

To meet the requirements in the treatment of constipation a therapeutic agent should have the following pre-requisites

1. It should supply bland bulk to a spastic colon, and stimulate peristalsis by gentle dilatation of the bowel
2. It should lubricate, facilitating passage of the intestinal content
3. It should have a viscous tenacity, in order to unite with fragmented stools when diarrhea is present
4. It should not irritate the sensitive gastrointestinal tract
5. It should not interfere with digestion
6. It should not leak from the anus when taken in quantities sufficient to afford the desired therapeutic effect.

All these are supplied by
MUCILOSE

Mucilose is a hemicellulose (vegetable gum) prepared by a special process from the *Plantago loeflingii*. It acts by holding water in the feces and producing a large, soft, pliable stool. Two forms are available, both easily taken—Mucilose Granules and Mucilose Flakes.

*Proves of special service in the treatment of
pus cases*

ENZYMOL resolves necrotic tissue, exerts a reparative action, dissipates foul odors; a physiological, enzymic surface action. It does not invade healthy tissue; does not damage the skin.

It is made ready for use, simply by the addition of water. These are simply notes of clinical application during many years:

Abscess cavities	Diabetic gangrene
Antrum operation	After removal of tonsils
Sinus cases	After tooth extraction
Corneal ulcer	Cleansing mastoid
Carbuncle	Middle ear
Rectal fistula	Cervicitis

Originated and Made by

FAIRCHILD BROTHERS & FOSTER
NEW YORK

Recent experimental work has shown that the production of toxic substances in the intestine associated with a deficiency of certain food substances in the diet may cause anemia, possibly of the hemolytic type. Such observations serve to emphasize the extraordinary importance of an adequate diet in maintaining normal health, and are a yet further indication of the close relationship of normal gastro-intestinal function to normal hemopoiesis.

Hanes Fowler, Fort Wayne.

ANNUAL MEETING OF AMERICAN CONGRESS OF PHYSICAL THERAPY

The 17th annual scientific and clinical session of the American Congress of Physical Therapy will be held co-operatively with the 22nd annual convention of the American Occupational Therapy Association, September 12, 13, 14 and 15, 1938, at the Palmer House, Chicago. Preceding these sessions, the Congress will conduct an intensive instruction seminar in physical therapy for physicians and technicians—September 7, 8, 9 and 10.

The convention proper will have numerous special program features, a variety of papers and addresses, clinical conferences, round table talks, and extensive scientific and technical exhibits.

The instruction seminar should prove of unusual interest to everyone interested in the fundamentals and in the newer advances in physical therapy. The faculty will be comprised of experienced teachers and clinicians; every subject in the physical therapy field will be covered. Information concerning the convention and the instruction seminar may be obtained by addressing: The American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago.

Vitamins in Relation to Gastro-Intestinal Diseases*

By

MARTIN G. VORHAUS, M.D.
NEW YORK, NEW YORK

THE interest of the general practitioner in vitamins is growing rapidly. A few years ago the prevailing medical attitude was one of cynical ignorance. Today, stimulated by a large and increasing scientific literature, spurred on by the high pressure salesmanship of pharmaceutical firms and acutely aware of the general public curiosity aroused by the daily press and magazine articles, the doctor is in danger of becoming over-enthusiastic in his haste to jump on the "vitamin band-wagon".

It is admitted that cases of beriberi, pellagra, sprue and other deficiency states do exist, even in our own communities, with somewhat greater frequency than has been believed. These cases can and should be recognized earlier and treated properly. But the vitamin problem of today is much more than the recognition of the most advanced stage of vitamin lack. There is a larger number of patients who are suffering from a mild or moderate vitamin deficiency. These are the cases that are most important to recognize and treat.

How shall we recognize the pre-clinical stages of vitamin deficiencies?

Why does avitaminosis become of special interest to a gastro-intestinal symposium?

These two questions form the basis of this discussion but it is necessary to answer them in the reverse order.

Since the vitamin content of the diet is the basis of our normal intake, it becomes important at the onset to discuss foods and the factors which influence the digestion, absorption and utilization of these food factors.

A state of vitamin deficiency—either clinical or pre-clinical—may develop under the following conditions:

1. When there is an inadequate amount of vitamins in the diet.
2. With an adequate amount of vitamins in the diet when there is, A. An increased need for vitamins. B. A diminished absorption of vitamins. C. An increased destruction of vitamins. D. A diminished utilization of vitamins.

A poor vitamin intake frequently exists for a long time before it can be recognized clinically. A variety of causes results in a diminished intake and can be classified as follows:

I. Errors in Eating.

1. Malnutrition due to economic factors.
2. Malnutrition due to dietary ignorance.

A. Fads in diet—such as weight reduction diets. B. Eccentricities in diet—such as excess of carbohydrates. C. Chronic alcoholism—replacing part of the diet. D. Self imposed diets for the relief of symptoms, such as anorexia, dyspepsia or dysphagia. E. Prolonged adherence to diets prescribed by physicians especially in the treatment of: Peptic ulcer, chronic

nephritis, chronic colitis, allergic states, biliary tract disease, cardiac diseases.

IIA. Even when the vitamin content of the diet is adequate, there are many exigencies which may develop and as a result the need for one or more of the vitamins is increased. If a greater supply is not furnished, either by the diet or by additions thereto, a state of clinical or pre-clinical avitaminosis may ensue.

An increased need for vitamins occurs in:

1. Growth.
2. Pregnancy and lactation.
3. Increased work.
4. Increased metabolism (hyperthyroidism).
5. Infectious and toxic states and their convalescence.

IIB. Although a given diet may contain adequate amounts of all vitamins, there are many factors which interfere with the absorption of these vitamins. These may be classified as follows:

A diminished absorption of vitamins occurs with:

1. Vomiting.
2. Diarrhea.
3. Alteration of the gastro-intestinal mucosa due to a. Atrophy. b. Inflammation. c. Circulatory disturbances.
4. Alteration of the gastro-intestinal secretions, namely a. Gastric. b. Biliary. c. Pancreatic. d. Intestinal.
5. Alteration of gastro-intestinal continuity by a. Surgery (short-circuiting operations). b. Internal fistulae—such as gastro-colic, etc. e. External fistulae—biliary, pancreatic, etc.

IIC. It is well known that certain vitamins are easily destroyed in the body and that although the diet is adequate in this respect, a state of deficiency may develop.

Increased destruction of vitamin may occur with: 1. Diminished or absent gastro-intestinal secretions. 2. Bacterial and chemical interactions.

IID. Finally, while the diet may be adequate and the factors of need, absorption and destruction have all been taken into account, there still remains the possibility that the cells of the body may not be able to utilize certain vitamins either in part or in toto.

Diminished utilization of vitamins may occur with:

1. Achylia.
2. Gastric resections—especially subtotal.
3. Advanced hepatic disease.
4. Advanced pancreatic disease.
5. Advanced renal disease (?).

It has not been proven that renal disease interferes with vitamin utilization but there is suggestive evidence in this respect, especially in relation to the nephrotic types of chronic renal disease.

This schematic representation of factors favoring vitamin deficiency conclusively demonstrates an intimate inter-relationship to gastro-intestinal disorders.

Once we are aware of this association, it becomes our responsibility to be on the lookout not only for the outspoken clinical syndromes of advanced avitaminosis but to recognize or at least suspect—the milder or pre-clinical deficiency states. With this in mind it is desirable to review some of the knowledge derived from animal experiments and to emphasize those factors which are particularly germane to our human problems.

*Read before the Gastro-Intestinal Department, Beth-El Hospital, Brooklyn, N. Y., February 21, 1938.
Submitted February 25, 1938.

When an animal is deprived entirely of a single vitamin, a disease state develops which is characteristic. The rate at which this experimental deficiency develops varies with different species as well as within members of the same species. It is modified by the preceding health of the animal as well as by the degree of storage of that and other vitamins in the body of the animal prior to the experiment. It is further influenced by the need of that animal for the vitamin in question—a need which is dependent upon growth, pregnancy, work, temperature and many other factors.

In spite of all these variables—known and unknown the complete absence of one vitamin in the diet of an animal is followed by a well recognized disease state. However, when an animal is given a diet deficient in one vitamin but in which that vitamin is not entirely absent, the observations of such an animal's state of health are less clear cut. In some instances a fairly well recognized pathologic state is observed yet often the experimental results vary considerably. Some animals may appear to remain well while others develop a group of bizarre signs which are difficult to explain or classify.

As an illustration of this point, Cowgill (6) points out that when dogs are kept on a diet markedly deficient in riboflavin (vitamin G), they develop a profound collapse in about four months. At this time if they are given riboflavin by parenteral injection, the dogs recover quickly. In six hours they are able to stand again and in twenty hours they can run around and appear to be normal. However, if dogs are kept on a diet which is less deficient in riboflavin (i. e. given one-half of the daily requirement of this vitamin) they do not develop the characteristic collapse. These dogs live eight months or longer and finally develop an ataxia with pathologic changes in the spinal cord.

This illustration by Cowgill is not an exceptional one. It has been repeated by many experimentors with the other vitamins in many different species. It is thus apparent that there is a considerable difference in the pathologic states of animals in which a single vitamin is completely withheld or in which a fraction of the daily requirement of that one vitamin is given.

In reviewing those animal experiments in which several vitamins are partially deficient in the diet, the differences in the observations of these animals become more marked and more confusing. Yet it is most frequently the case that the patient who seeks help is more likely to be partially deficient in several vitamins rather than to lack only one.

Clinical counterparts of these animal experiments are being recognized. Recently the photometer has demonstrated that the physician does not need to wait for xerophthalmia to diagnose a vitamin A deficiency. Even the symptom of night blindness may not be present. Recent photometric tests have shown a partial deficiency of vitamin A in 50% of a group of adult ambulatory out-patients (5).

Unfortunately there has not yet been developed a similar simple method for the determination of sub-clinical stages of the other vitamin deficiencies. But the lessons of animal experimentation teach us not to look only for the well developed picture of acute or complete avitaminosis such as beriberi or scurvy. It is exceptional for man to exist under conditions of complete or almost complete absence of any one vitamin. The much more frequent clinical state is one of

mild or partial deficiency of one or several vitamins over a long period of time.

At present the published clinical papers seem to be more concerned with case reports of instances of advanced vitamin deficiency occurring in some other disease. An illustrative collection of such case reports is tabulated.

VITAMIN A DEFICIENCY

With extensive hepatic disease—Blegvad (2).

With gastro-colic fistula—Wilbur and Snell (19).

With congenital atresia of bile ducts—Altschule (1).

VITAMIN B DEFICIENCY—THIAMIN

With side tracking of most of small intestines—Urmey et al. (18).

With post operative ileal stricture—Jones (11).

With ulcerative colitis and hyperthyroidism—Jones (11).

With jaundice due to stones in common duct—McVicar (14).

VITAMIN C DEFICIENCY—ASCORBIC ACID

With prolonged use of diet for duodenal ulcer—Jones (11).

With prolonged use of diet for ulcerative colitis—Jones (11).

With chronic jaundice—Many authors (9, 12, 17).

VITAMIN G DEFICIENCY—RIBOFLAVIN

With diffuse gastro-enteritis—Wilbur and Snell (19).

With rectal diarrhea—Boggs and Podget (3).

SPRUE

With extensive atrophy of intestinal mucosa—Snell (16).

With carcinoma or atrophy of pancreas—Snell (16).

With gastro-colic fistula—Snell (16).

With tuberculosis of lymph nodes—Snell (16).

With prolonged diet after resection for carcinoma of tongue—Jones (11).

These case reports are the counterpart of animal experiments especially where complete or almost complete absence of one vitamin has been instituted. In addition to animal observations, further information regarding vitamins has been procured by another method—namely that of feeding large amounts of vitamins to human subjects. In this manner Jolliffe (10, 7) and his co-workers have conclusively proven that alcoholic polyneuritis is not due to alcohol but is a vitamin deficiency due to lack of thiamin (vitamin B). Similarly Carroll (4) has demonstrated that in tobacco-alcohol amblyopia the addition of multiple vitamins to the diet results in a large percentage of marked improvement even though the use of tobacco and alcohol is continued.

MacKie (13) reports an interesting group of cases of ulcerative colitis in which 62.6% had symptoms which could be interpreted as evidence of deficiency states.

Similar reports (8) are being published which increase our awareness of the frequency with which mild deficiency states may be associated with gastro-intestinal diseases. With this in mind, it becomes important to recheck constantly the vitamin content of

those patients' diets who require long continued food restrictions.

Vitamin A rich foods are: spinach, escarole, greens, carrots, butter, eggs, cream and liver. If these foods must be restricted in the diet, the necessary vitamin A can easily be replaced by one of the many fish liver oil preparations.

The daily adult requirement of vitamin A is about 5000 international units.

Vitamin B—Thiamin is the one vitamin most likely to be deficient in the average diet. It is present in fairly good amounts in relatively few food stuffs. In addition Thiamin is heat labile and water soluble. Cooking destroys some of this vitamin but under usual conditions only a small amount is lost this way. A larger amount of this vitamin is wasted by discarding the water in which foods are cooked.

Coarse grains contain a large amount of Thiamin especially wheat germ. Whole wheat has more than six times the amount of this vitamin than is found in white flour, while wheat germ is almost fifty times richer than flour.

Milk and eggs contain good amounts of Thiamin but it is well to keep in mind that if the patient depends upon these foods alone for this vitamin, he must ingest over two quarts of milk or forty eggs daily to insure minimal requirements. Among the meats the largest Thiamin content is in lean pork and in beef liver. Interestingly enough, lean pork has seven times more of this vitamin than beef. Other foods with a fair amount of Thiamin are kidney beans, peanuts, dried peas, brown rice and crude cane molasses.

The daily adult requirement of Thiamin is from 1 to 2 mgms. but usually up to 4 mgms. may be needed in health.

Vitamin C—Ascorbic Acid is derived mainly from citrus fruits, also spinach, peppers, turnips, greens and parsley.

It is also water soluble and heat labile.

The daily adult requirement of Ascorbic Acid is from 40 to 60 mgms.

Vitamin D is not included in our consideration since it appears to have no relationship to gastro-intestinal disorders.

Vitamin G—Riboflavin is derived mainly from liver, kidney, milk, eggs, prunes, wheat germ and tangerines. Yeast is also a very good source of this vitamin.

The daily adult requirement has not yet been adequately determined.

After having checked the diet of a patient, the physician must depend upon his clinical judgement for the diagnosis of milder deficiency states. One important aid in the diagnosis is the tongue. A careful examination of the tongue often offers the first clue. The red tongue of sprue, the bald tongue of macrocytic anemias, the swollen tongue so often but not constantly encountered in pellagra are early signs and can be recognized often before other clinical symptoms and signs are available. Careful scrutiny of the mouth will show at times early signs of gingivitis or beginning bleeding which should arouse the suspicion of a vitamin C deficiency.

The presence of a persistent diarrhea—even though mild—might be the first symptom of early pellagra and its presence should encourage the physician to look for early skin lesions, especially on the backs of the hands and on the face and neck.

Unexplained loss of appetite is occasionally the first

symptom of a B deficiency but unfortunately anorexia is also the first symptom of many slowly developing organic or psychic disorders. Vague but persistent pains in the legs, recurrent attacks of back pain or stiff neck in an obese individual warrant a clinical suspicion of vitamin B deficiency.

And finally the laboratory may add some suggestive information towards the solution of these clinical problems. Unexplained anemias, especially of the macrocytic type—even though mild—should receive careful consideration from the clinician, and the X-ray finding of osteoporosis in a young or middle-aged individual may well be an early indication of avitaminosis.

In addition it is well to remember a note of warning from those workers in the animal field who remind us that the members of a species larger in weight or height than the average, have a proportionally greater vitamin requirement.

A great deal of attention is directed repeatedly to the increased vitamin needs during growth and pregnancy but not enough stress has been laid upon the equally increased vitamin requirements of patients with hyperthyroidism, cirrhosis of the liver, diabetes, gout and chronic osteoarthritis, as well as the needs of the normal man or woman who is constantly overworking—either physically or mentally.

There is one more point to discuss before closing, and that is the relationship of vitamin lack to pre-operative preparation of the patient. It has been axiomatic in our better hospitals for the surgeon to invite the co-operation of the internist in preparing many patients for operation. This is particularly true in cases of diabetes and cardiac disease. Recently Means (15) has stressed this need in the pre-operative preparation of thyroid patients. In this respect the use of iodine is only one factor but of equal importance is the replenishing of the vitamin lack. Means has shown a decided drop in mortality from surgery after instituting this regime.

Too few surgeons have this point of view in regard to severe gastro-intestinal diseases. Repeatedly operations are performed in the presence of chronic diseases associated with deficiency states with no other pre-operative preparation than a transfusion. This is true especially in cases of chronic peptic ulcer, slowly developing gastro-intestinal carcinoma and chronic biliary tract disease with low grade infection and liver involvement. Extensive intestinal surgery is performed upon patients with chronic regional ileocolitis with little or no thought of bringing the vitamin lack up to normal.

As surgeons become more aware that vitamin deficiency states have a very important prognostic significance, the internist will be given more opportunities to adequately prepare a patient for operation. With a reduction in operative mortality in all hospitals—as has been the case in a few already—the use of the term "shock" as the cause of death will show a marked decline.

CONCLUSION

A state of ill health is often the result of a faulty diet but even in the presence of a normal diet, deficiency states may develop. The awareness of avitaminosis will often direct the internist to recognize the outspoken clinical states and to suspect the pre-clinical stages of vitamin deficiencies.

Studies on the Parallel Action of Vitamin C and Calcium

By

SIMON L. RUSKIN, M.D.
NEW YORK, NEW YORK

THE synthesis of cevitamic acid has made possible not only further physiologic study of Vitamin C action but also its chemical role. In a general way the relationship of action between Vitamin C and calcium has been assumed. It is, therefore, significant to point out the direct chemical relationship between the two.

Calcium, forming the architectonic tissue of the body, is essentially a highly insoluble ion at biologic Ph ranges. As the carbonate, it is one of the most insoluble of substances. Its solubility is somewhat influenced by CO_2 , by parathyroid hormone and the hydrochloric acid of the stomach. In the absorption of calcium from the small intestine, none of these factors are present. It was, therefore, essential to find some other agent possessing solubilizing properties for calcium.

In the course of my chemical studies on Vitamin C, I was surprised to find that Vitamin C could dissolve the insoluble calcium carbonate with a rapidity and completeness second only to fairly strong hydrochloric acid. For a biologic acid this action was unique and quite unexpected since gluconic acid which is a sugar quite similar in structure but differing in the double bond and two hydrogen atoms, forms a solution of calcium only to 3% as the calcium gluconate. By special stabilizing procedure, supersaturated solutions up to 10% are formed and through the glucono gluconate 20% solutions are attained. It was, therefore, striking to find that cevitamic acid formed 100% solutions of calcium and in fact was hygroscopic. This marked solubility suggested the possibility of a strong ionizing influence on calcium and a series of experiments were carried out with the following results. As a basis of comparison the most soluble injectable salts were taken, that is, the calcium gluconate and calcium galactate gluconate.

The formula of Calcium Cevitamate, and its close relationship to gluconate, is graphically demonstrated in the accompanying illustration. One notes that there is a difference of two hydrogen atoms, and the pres-

ence of a double bond in the cevitamate giving it the oxidation reduction properties.

Calcium Cevitamate

Calcium Gluconate

It is a yellowish white amorphous powder manifesting a ready solubility, making it available in physiologic solutions up to (40%). It is non-irritating on injection, either subcutaneously, intramuscularly or intravenously, and is well tolerated by the gastro-intestinal tract.

In view of the marked solubility of Calcium Cevitamate, a difference in ionization of the two salts suggested itself and the following experiments were performed and the results recorded.

A comparison of the ionization of the two salts is as follows:

Salt	% Solution by Weight	Concentration Moles/Liter	Temperature Drop °C.	% Ionization	Yield Ca ion Per Gram Salt	Yield Ca ion Per cc. Solution
Calcium Cevitamate	5%	.123	.577	74.6	.0700	.0037
"	10%	.261	1.085	60.0	.0563	.0063
"	20%	.589	2.362	58.1	.0546	.0137
"	30%	1.008	3.940	55.3	.0528	.0226
Neo-Gluconate	10%	.125	.565	*47.8	.0323	.0048
"	20%	.273	1.120	*40.3	.0273	.0088
Calgluconate	3%	.072	.263	48.6	.0452	.0014

*Since the structure of the Neo-Calgluconate is not known, and since its empirical formula is $(C_{26}H_{44}O_{28}) Ca_2$, we have assumed that it ionizes as follows: $Ca_2C_{26}H_{44}O_{28} \longrightarrow 2 Ca \quad 2(C_{13}H_{22}O_{14})$

An analysis of these findings would tend to indicate that the Calcium Cevitamate in 5% solution was approximately equivalent to the neo-gluconate in 10% solution and that the 10% Calcium Cevitamate was approximately equivalent to the 20% neo-gluconate.

The comparative series was run only to 30% Calcium Cevitamate because the neo-gluconate solutions do not exceed 20%. In considering the calglucon tablet which is only 3% soluble the yield of calcium ions per cc. of solution was .0014 whereas that of the Calcium Cevitamate in only 30% solution was .0226 or about twenty times greater. If calculated on the basis of 100% it would be in the vicinity of sixty times greater in calcium ion content per cc. solution. How important this factor can be in the question of calcium absorbability becomes apparent from the volume of solute necessary to obtain an equal amount of available calcium. For every 100 cc. of solute required for the absorption of Calcium Cevitamate it would require 6000 cc. of solute for an equal availability of calcium in gluconate. Since the total fluid content of the gastro-intestinal canal is about 5000 cc. and absorption of calcium occurs only in the upper intestine, the difference in absorbability between Calcium Cevitamate and calcium gluconate becomes apparent.

The action of cevitic acid on the ionization of calcium opens up a field both of theory and practice. A comparison of the physiologic action of cevitic acid and calcium shows an almost completely parallel action in bone metabolism, hemorrhagic diathesis, cell membrane permeability and detoxicating action. So close is this resemblance that one can interchange their functions. It is this element which suggests that cevitic acid may be the factor which acts as the vehicle for the diffusible fraction of the serum calcium. There is a strong probability that the parathyroid hormone and cevitic acid jointly balance the small fraction of

ionized diffusible calcium. Greenwald is quoted by Cantarow as suggesting that some of the calcium is bound to an organic substance in a citric like combination, the compound being intimately connected with the parathyroid hormone probably diffusible and slightly ionized. Belief in the existence of such a compound is also shared by Klinke and by Dendroy and Hastings. The latter drew attention to the similarity of action of the parathyroid hormone and citrate solutions in holding calcium in solution. In view of the fact that calcium citrate is only .8% soluble it is difficult to conceive of citrate as a calcium solubilizing

agent. Cevitic acid, however, has precisely the desired action on the ionization of calcium and its distribution in the intestinal canal, pituitary and adrenal makes it a much better hypothetical agent than citrate.

From the practical aspect it is important to note that the injection of Calcium Cevitamate is non-irritating and better tolerated than gluconate.

We may summarize the parallel action of calcium and vitamin C as follows:

1. Alter cell permeability.
2. Inhibit, exudates and transudates.
3. Decrease nerve irritability.
4. Increase coagulability of blood.
5. Inhibit allergic reactions.
6. Possesses a detoxicating action on heavy metals, and arsenic.
7. Participates in tooth and bone growth.

Thus, Borbely has shown that after a calcium injection it takes a much longer time and stronger suction to produce intradermal hemorrhage in an area of skin covered by a suction cup. Gothlin (?) used the same test for determining Vitamin C deficiency clinically.

In describing capillary hemorrhages, as the consequences of vascular congestion in the course of chronic infections, and the cause of hemorrhagic symptoms in acute infectious diseases, Kugelmass (4) has recommended the use of Calcium. On the other hand, Lundeidei (5) showed that large doses of ascorbic acid have a favorable influence in hemorrhagic conditions. Lamin (6) demonstrated that bleeding time in rabbits was decreased 17-22% less than an hour after the injection.

A remarkable similarity in physiologic action exists between calcium and Vitamin C in various diseases which I will describe briefly. Their actions in allergy are so alike as to make Calcium Cevitamate a double acting agent with the same physiologic re-

sponse and, at the same time, securing an intensification of calcium action hitherto unobtainable in similar dosage. To indicate the variety of applications, we find that in the treatment of purpura hemorrhagica for which calcium is commonly used, A. Sa and O. A. Prestera (8) attributed the recovery to a subsidence of Vitamin C deficiency. In tooth and bone growth, where calcium plays a dominant role, Vitamin C has been demonstrated to be a vital partner without which normal calcium metabolism could not be maintained as shown by A. A. Mikhailova (9).

The diuretic action of calcium, in acute and chronic nephritis, nephrosis and ascites, is also possessed by Vitamin C as described by M. A. Abbasy (10). He showed under carefully controlled conditions, that Vitamin C possessed a specific diuretic effect on human beings. Another physiologic action common to both Vitamin C and calcium is their effect on the vegetative nervous system. Calcium diminishes neuromuscular irritability, and vasomotor instability. Tislowitz (11) demonstrated in dogs that the injection of large doses of ascorbic acid caused a slowing of the heart beat, a decrease of 0.5° - 1.0° in body temperature, and a 10% increase in the alkali reserve. Conversely, it was shown by Sankaren and Krioluman (12) that guinea pigs on a diet, deficient in Vitamin C, developed tachycardia.

Again in tuberculosis, especially of the intestinal type, calcium has been favorably employed in reducing the diarrhea, and causing improvement of the local condition. Here too Vitamin C plays a similar role and has been claimed by Heinemann (13) to protect guinea pigs infected with tubercle bacilli against intestinal tuberculosis. Likewise, Petter (14) describes definite improvement in tuberculosis patients following administration of Vitamin C.

In adult rabbits, sensitized to horse serum, anaphylactic shock was entirely prevented, or its severity greatly decreased by the intravenous injection of 100 mg. cevitamic acid given 1-5 minutes before the shock injection. A. Hochwald (15) also showed that cevitamic acid in large amounts injected intravenously was therapeutic in hyper-sensitive states in human beings, and inhibits histamine shock. It has also been shown that diphtheria toxin and benzene poisoning are neutralized by Vitamin C; similarly, arsphenamine intoxication is combated by both cevitamic acid and calcium as shown by Otto Klin (16) and A. Meyer (17). F. Widenbaur and S. Saretz (18) describes the antitoxic activity of Vitamin C on Diphtheria toxin in man. Marion B. Sulzberger and Bernard L. Oser (19) showed the influence of Ascorbic Acid in Diet on Sensitization of Guinea Pigs to Neoarsphenamines. Important in this detoxicating mechanism are the oxidation reduction properties possessed by cevitamic acid through the action of the double bond. Thus, Klodt (20) suggests that the oxidized ascorbic acid, under low tension gives up its O to the hemoglobin-oxhemoglobin. Holtz (21) also speaks of ascorbic acid as an oxidation catalyst for unsaturated fat acids. How important this factor is in calcium metabolism becomes apparent from Cantarow's statement that "Disturbances of fat absorption act in impairing calcium absorption since the presence of large amounts of fatty acids in the intestine results in the formation of calcium soaps which being insoluble, are not absorbed and are eliminated in the feces." This disturbance has received too little at-

tention from those advocating large doses of calcium gluconate by mouth.

All of the above properties are possessed as well by calcium as by Vitamin C in striking parallel action.

Jungeblut (22) has also suggested the use of cevitamic acid in the prophylaxis of poliomyelitis because of its apparent virucidal action.

Another important relationship worth emphasizing, is that which exists between the adrenalin mechanism and Vitamin C. Cislighi (23) demonstrated certain similarities of the effects of 1-ascorbic acid, and adrenalin leading him to suggest that the vitamin stimulates adrenalin secretion. The role of ascorbic acid in oxidative processes is discussed. R. Tislowi (24) further showed that ascorbic acid caused a decreased blood volume, slight diuresis, a slight drop in the body temperature, increased vascular tonus, and has a vagotonic action on the circulation. He considers that its use in conjunction with the adrenal cortical hormone, or pituitary hormone, in dynamic states particularly of the circulation, is indicated.

Studying the calcium question further, we find that the blood calcium is contained entirely in the plasma, and appears in two forms: A diffusible Ca, and non-diffusible Ca, each about 4.5 mg. per 100 cc. The diffusible will pass thru a dialyzing membrane, and would be able to pass thru the living capillary wall or cell membrane. The non-diffusible would not. Of the diffusible 4.5 mg. Ca only about 2 mg. is ionized or electrically charged and probably represents the vitally active form of calcium while the insoluble forms of calcium such as the phosphates and carbonates go to supply the structural framework of the body.

Thus we see that the immense amount of body calcium is mobilized in the ionized state in a very small amount by some physiologic agent that must not be cumulative to avoid too great a solubilizing action. Such an agent is ideally found in Vitamin C which is not stored in the tissues in a supply greater than that which would suffice for 2-3 weeks, after which period there set in symptoms of scurvy. Also, it is a sugar which is readily burned or excreted in the urine. The average total of ionized calcium in the blood stream if calculated at five liters, would be about 100 mgs. or about the daily consumption of Vitamin C. The rate of excretion of cevitamic acid above those amounts would vary with the calcium needs of the body. Thus, in tuberculosis where healing occurs by calcification entailing the mobilization of calcium to the lesion, the excretion of Vitamin C is markedly reduced. Vitamin C is also uniquely fitted to avoid protracted storage in the tissue. Just as parenteral calcium is thrown out almost completely in 72 hours, so also is the structure of cevitamic acid so labile that it is most easily oxidized or reduced and is in addition autooxidizable, thus requiring continuous replacement. In fevers the Vitamin C requirement rises rapidly and hemorrhagic processes complicating protracted illnesses have been viewed from the angle of relative depletion of Vitamin C. Thus Calcium Cevitamate is not merely a mixture of two similarly acting substances, but the finished product of the proper vehicle for calcium where physiologic action is required, and marks a step forward in calcium therapy.

Aside from its vehicle action for calcium, Vitamin C apparently plays a role in the endocrine set-up. Its occurrence in the pituitary in larger amounts than in

other tissues, suggests a relationship there, and its adrenalin stimulating action speak for an endocrine influence.

SUMMARY

1. The parallelism of calcium and Vitamin C action leads to the assumption of a community of action.
2. The chemical properties of cevitic acid would

indicate that it is the stabilizing agent for calcium in the body, participating in absorption and the maintenance of the ionized calcium in serum calcium.

3. A new therapeutic agent for calcium therapy has evolved which possesses the marked advantages of greater solubility, absorbability and complete calcium action.

The Passage of Gall Stones Through the Sphincter of Oddi*

By

MARIE ORTMAYER, M.D.†

and

MARGARET AUSTIN, M.D.‡

CHICAGO, ILLINOIS

THE search for gall stones in the feces, among the procedures to establish a diagnosis of Cholelithiasis has been regarded as practically useless for several decades and, beginning with the development of the modern roentgen method of gall bladder visualization, has usually been omitted. This paper reports three patients from whose stools gall stones were recovered which passed the sphincter of Oddi during attacks of pain in the right upper quadrant associated with jaundice. An attack of colic during convalescence from cholecystectomy prompted the search for stone in the first patient, while in the second deliberate experimentation with antispasmodic drugs instituted the methodical examination of all stools. The third patient, a physician, in whom the diagnosis of gall stones was only suspected, examined the stools for corroboration.

Case 1. A 70-year-old woman had her first attack of epigastric distress three months before coming to operation. Four succeeding attacks occurred, some of greater severity, with characteristic right upper quadrant pain, requiring morphine for relief, one accompanied by mild icterus.

Examination, three weeks, later, revealed only mild tenderness over the gall bladder region. The gastro-intestinal

investigation was completely negative except for two non-visualizations of the gall bladder by the oral method.

At Cholecystectomy, the gall bladder was found to be small, thickened and adherent to the liver and and was dissected free with difficulty. It contained some thick dark bile and about 27 stones, 20 of which were dark brown, soft, and of grapeseed size, while the remainder

Gall stone recovered from stool of patient at termination of an attack of colic and jaundice which developed eight days after operative removal of gall bladder.

were half again as large and firm. Laid on a film and X-rayed, none cast shadows.

On the eighth post-operative day, the patient complained of abdominal distension with mild epigastric burning; the latter increased in intensity. In 48 hours the patient was moderately jaundiced, the stools were light yellow and the urine contained excess of bile. The following day excre-

Submitted February 17, 1938.

ciating non-radiating colicky pain in the epigastrium developed and persisted with intervals of greater intensity. The pain was only mildly improved by atropin and benzedrin and was finally controlled by morphine without recurrence. The jaundice became deep and the stools acholic. All stools were examined for stones and on the fourteenth post-operative day, 6 days after the attack, in the last acholic stool one grape-seed sized stone was recovered identical with those present in the gall bladder at operation (Fig. 1). Bile appeared in the next stool. No

Gall stones recovered from the stools of patient 2.
(About $\frac{1}{2}$ actual size)

other stones were found. The remainder of the convalescence was rapid and uneventful.

Case 2. A woman of 60 years had been ill for two years with cardiac disease requiring treatment with amyl nitrite and later digitalis. On November first, 1937, she developed symptoms, "which were quite different from her heart attacks" and which she had had only twice before: "severely in February, 1937, for six hours and less severely a month later." The third attack began with an epigastric discomfort several nights in succession for which the physician was not called until the third evening. The patient was then slightly jaundiced, had a fever of 100 degrees, was tender in the epigastrium with right upper rectus rigidity and bile excess in the urine. The low-grade fever, considerable toxicity, increasing jaundice and light colored stools continued five days, and receded by the fourteenth day. A film, without dye, of the gall bladder region revealed no calcified shadows. The diagnosis was Acute Cholecystitis.

The patient then began to have nocturnal attacks of chill and fever with recurrence of jaundice. The temperature rose above 102 at night and dropped to normal by morning. This was repeated four times from November twentieth through the twenty-fifth and justified a diagnosis of Common Duct Stone. The patient was clear mentally in spite of these sharp bouts and felt less sick than during the earlier time with lower fever. Operation was thought unwise because of the cardiac condition.

Benzedrin and magnesium sulphate were given as follows:

	Benzedrin	Mag. Sulph.
11 20	10 mgm.	
11 21		Z 1
11 24	20 mgm.	Z 1
11 25	30 mgm.	

A short period of low fever and slight jaundice without chill recurred 11 27-11/28. Then suddenly 12/1/37 the patient felt and seemed much improved. The inconspicuous character of the pain at all times should be stressed.

A consistent search for stone in the feces was begun and continued for a month. Calculi were found as follows:

Date	STOOL EXAMINATIONS	Number of Stools	Color	Calculi
11/13-11, 19				
11/21			brown	0
11/23			gray	0
11/24			clay	0
11/26			clay	0
11/28			yellow	0
		1	light brown	0
12/1		1	clay	0
12/2		2	putty color	0
12/3		1	putty color	0
		1	putty color	4
		1	yellowish	2
12/4		1	yellow	0
		1	brown	1
12/5		1	"	0
12/6		2	"	0
		1	"	1
12/7		1	"	0
12/8		1	"	1
12/9		1	"	0
12/10		1	"	1
12/11		1	"	0
12/12		1	"	0

Ten in all were recovered and, as is noted, by no means in consecutive stools. The photograph shows the uniform size of these stones and the definite facetting. (Fig. 2).

Case 3. A well-nourished woman of 62 years, a physician, gave a gastro-intestinal history of one attack of epigastric pain 30 years previously, diagnosed Acute Gastritis, and a long-succeeding period of achlorhydria for which she took dilute hydrochloric acid.

One night, six hours after an ordinary dinner, the patient awakened with epigastric distress, dull and burning, accompanied by nausea and followed within three hours by vomiting. This episode was of about 10 hours duration. For the next few days the patient was unable to eat more than the simplest carbohydrates without precipitating epigastric distress, nausea and vomiting. When, finally, even water was not tolerated and the patient became dehydrated, a physician was called.

At this time, on the sixth day following the first appearance of symptoms, the patient was mildly jaundiced and had definite tenderness in the right upper quadrant. The stools were light and the urine dark with bile. The icterus index was 14. A few stools became acholic. The clinical diagnosis was Common Duct Obstruction. It was suggested that the stools be watched for stones. Nine small faceted

Seven of the nine stones recovered from the stools of patient 3. The remaining two were of the size of the smallest of these. The gall bladder, at operation, was half full of similar sized stones.

stones were recovered in the next five days. (Fig. 3). Some of them, when photographed, cast shadows on X-ray films. Altogether the attack lasted ten days. Subsequently films, following the dye by mouth, failed to visualize the gall bladder or any calcifications. At operation, a thickened gall bladder, half full of stones of the size and shape as shown in Figure 3, was removed. No stones were found in the common duct, though thorough search was made.

The recovery of gall stones from the feces of three patients, who presented themselves for diagnosis with-

in a short time interval, introduces the query if gall stones do not pass the sphincter of Oddi more frequently than is generally believed. It must be admitted that stones of pea-size or under could pass the relaxed sphincter (1, 6). Recent textbooks (3, 11, 15) mention this possibility and the older clinicians, who did not have X-ray at their command, give varying percentages of recovery of calculi from feces. Rolleston (13) states that biliary calculi "not uncommonly" pass when an attack of biliary colic is precipitated at the beginning of a course at Carlsbad, and adds that Kehr (7) puts the recovery of biliary calculi from feces as high as 25%. **Mayo Robson (12), on the other hand, states that they are seldom found. Most clinicians in the last two decades, though concerned with refinements for diagnosis, such as microscopic increase of crystals in duodenal drainage and the origins of different bile fractions, neglect or scorn gross stool examination for stone (2, 4, 8, 9, 11). In contrast, the lay public is always finding and bringing, bottled in alcohol, inconsequential exhibits from the stools and have, in times past, when olive oil was supposed to cure gall bladder disease, brought in "stones" shown to be nothing but inspissated oil. The patient properly instructed in the technic of how and what to look for would, no doubt, cooperate.

One may ask, if Kehr's quoted statistics are right, why stones are not more frequently found when searched for. Aside from the obvious explanation of their being missed or unrecognized when very small, two factors may account for this. Only stones in the common duct could pass into the duodenum and it is not always easy to make a differential diagnosis between stone confined to the cystic duct or gall bladder and common duct stone. Secondly, after stone enters the intestine, the delay in that tract is variable. Although in two of our cases stones were found when the stools were still claycolored or very light, in the second, six came down slowly over a period of days. Instances are cited of small gall stones which must have tarried in the bowel a long time and which have formed the center core of fecoliths, which have finally obstructed the bowel (14). In suitable cases where a search is to be made a saline cathartic is probably indicated. Magnesium sulphate by mouth should be as effective as Carlsbad water after an attack of colic, and, especially in the presence of achlorhydria, may be as relaxing to the duodenum as by instillation through the duodenal tube (16).

Another surmise suggested by our unoperated patient is whether a fistula could possibly have been present to permit the passage of stones into the bowel. The patient was unaware of a long-standing history of gall-

* See Ref. 13, p. 790. The authors could not verify this figure. Hans Eppinger in his book, "Die Leberkrankheiten," Julius Springer, Vienna, 1937, gives the following percentages of the frequency of the passage of gall stones into the bowel:

Goldammer	5.2%
Fink	11%
Kehr	9.3%

Whether these figures include stones passed through artificial as well as natural opening is not clear from Eppinger's text, but from a work of Kehr's, "Die Praxis der Gallenwege Chirurgen," Munchen, J. F. Lehmann, 1913, p. 214, it seems likely his 9.3% referred to stones passing through the sphincter of oddi, not through false passages.

tract disease. Judd and Burden (5) have stressed the long duration and severity of symptoms in patients in whom they found internal biliary fistulae at operation. One must however balance against this Naunyn's (10) statement that ulcerations of gall stones into the intestine may occur in 75% of patients without symptoms! In two other patients, recently seen by one of us, whose histories are not given and who had proven internal biliary fistulae, the attacks preceding the passage of stone were very severe and prolonged. In one the stone recovered measured 1½ by ¾ inches. To the authors it seems more likely that the ten stones found in the second patient reported herein passed the common duct sphincter.***

Recognition of this latter possibility not only allows of an explanation for an attack of severe distress resembling gall stone colic occurring but once in the life of an occasional patient, in whom thereafter by every means at our disposal no further gall stones are demonstrated, but stimulates to a systematic search for stone in the feces, if there is a reasonable suspicion that common duct stone is present. If stones pass the sphincter of Oddi fairly frequently, it permits greater hesitation in patients unsuitable for operation for other reasons, especially when these patients are advanced in years. A trial period of drugs of the duodenum or sphincter relaxing types could be instituted before advising difficult or even dangerous common duct surgery.

In closing, it must be stressed that the recovery of gall stones from the feces in no way assures that all stones have been evacuated from the biliary tract. Operation will of course remain, in the vast majority of patients, the surest method for the removal of gall stones and, when the gall bladder is seriously diseased, the most effective way of dealing with it.

CONCLUSIONS

1. The authors have reviewed the case histories of three patients from whose feces gall stones were recovered following attacks of right upper quadrant pain with jaundice. These stones were small enough to have passed through the sphincter of Oddi and did so with certainty in all three.

2. A short discussion follows, mentioning the literature on the relative frequency of the passage of gall stones through the natural openings and the neglect of the search for stone in the feces as a diagnostic procedure.

3. It is suggested that where stone in the common duct is suspected, evacuation into the duodenum by suitable drugs may be tried in suitable cases before difficult or dangerous common duct surgery is instituted.

4. Finally it is stressed that the recovery of gall stones from the feces does not guarantee complete evacuation of stones from the biliary tract and that surgery remains the surest method for their removal and the most effective for dealing with a seriously diseased gall bladder.

***Autopsy recently confirmed this judgment. No biliary fistula and no stones in the common duct were present. A considerable number of faceted stones like those in Fig. 2 were present in the gall bladder.

Infra-Red Photography of the Abdominal Wall in Portal Cirrhosis of the Liver*

By

I. R. JANKELSON, M.D.

and

HENRY BAKER

BOSTON, MASSACHUSETTS

SINCE the infra-red photographic plates are made on a production basis, this type of photography has assumed considerable prominence in scenic photography, industry and science. Very little expense is involved in the equipment except the specially prepared infra-red sensitive plates, which cost somewhat more than the ordinary photographic plates or films. Any ordinary good camera, equipped with plate-holders not transparent to infra-red rays, can be used. However, since the infra-red plates are sensitive to the violet and blue regions of the spectrum and to ultra-violet rays, it is

Since the infra-red rays penetrate the superficial layers of the skin, infra-red photography may show some pathologic condition of the subsurface of the skin not visible to the naked eye or on the ordinary photographic plate or film. Of particular value in medicine is the visualization of superficial veins, their course and the demonstration of possible enlargement, tortuosity and or anastomoses. The arteries remain invisible. The demonstration of the superficial veins of the extremities with the aid of infra-red photography has added much to our knowledge of peripheral vascu-

Plate I. Ordinary photograph on the left (picture B) and infra-red photograph on the right (picture A) of the abdomen of a normal individual. Note the absence of demonstrable veins on picture B over the dome of the abdomen.

necessary to use a filter which absorbs these rays, but transmits the infra-red ones. A good source of light for in-door photography can be supplied by an incandescent tungsten filament or a photoflood lamp.

The infra-red rays, because of the greater wave length, are absorbed by and reflected from various surfaces differently than the visible rays. They also have the power to penetrate hazy or opaque layers and substances. Thus are explained the remarkably clear long-distance scenic pictures obtained by this method of photography.

lar diseases, especially varicose veins. Other uses, to which this method of photography has been applied in medicine include (a) the demonstration of the contour and size of the pupil as seen through a dense cornea (1); (b) photography of thicker microscopic sections and of injected gross specimens, showing details of internal structure not always visible on ordinary photomicrographs or films (2); (c) photography of blood samples in order to determine the presence of CO-hemoglobin or reduced blood (3).

We attempted to demonstrate changes of the veins of the abdominal wall in portal cirrhosis of the liver. In this condition there is established a collateral circulation because of the portal hypertension which accom-

*From First and Third Medical (Tufts teaching) services Boston City Hospital. Aided by the Charlton fund of Tufts College Medical School. These photographs were a part of our scientific exhibit at the A. M. A. convention at Atlantic City in June, 1937. Submitted February 21, 1938.

Plate II Eight months pregnancy The infra-red photograph (on right) shows enlargement of the superficial veins of the abdomen. Note the lack of anastomoses. On the left is an ordinary film of the same case showing no demonstrable superficial veins.

Plate III Cardiac cirrhosis with ascites. On the right is an infra-red photograph showing enlarged dilated veins with a coarse network of anastomoses. On the left is an ordinary film of the same case showing no demonstrable superficial veins.

Plate IV. Cirrhosis of the liver with ascites. On the right is an infra-red photograph of the abdomen showing enlargement and tortuosity of the superficial veins. Note the fine network of anastomoses. On the left is an ordinary film of the same case showing no demonstrable superficial veins.

Plate V. Cirrhosis of the liver without ascites. On the right is an infra-red photograph of the abdomen showing enlargement and tortuosity of the superficial veins. Note the fine network of anastomoses. On the left is an ordinary film of the same case showing no demonstrable superficial veins.

anies it whether ascites is present or not. In order to establish the pathogenicity of a change in the pattern of the superficial abdominal veins we have photographed the abdomen of normal individuals, patients with various abdominal diseases, those with cardiac decompensation, some pregnancies in various stages as well as patients with definite or questionable portal cirrhosis of the liver.

The following technique is used by us. With the patient in the erect or recumbent position, the abdomen is exposed. For illumination two kodalites with 500 watt lamps are used, placed one on each side of the patient at a distance of about three feet. We use an Eastman clinical camera equipped with an astigmatic lens over which is placed a No. 25A Wratten filter. The focussing is done with the filter in place. There should be no movement or breathing while the photograph is taken. The Eastman Kodak infra-red plates loaded and developed in total darkness have proved

ordinary photographic plates or films. Whether the veins are visible or not, infra-red photography demonstrates these veins as enlarged, at times tortuous dark lines, showing few or no anastomoses. For illustration we show representative cases of pregnancy (Plate II) and cardiac cirrhosis with ascites (Plate III).

In the presence of portal hypertension, as in portal cirrhosis of the liver with or without ascites, new anastomoses between the portal and general venous systems are established. Thus varicosities of the veins of the esophagus, cardiac end of the stomach, and of the rectum are developed. There are also established some anastomoses between the veins of the portal system and those of the abdominal wall. The result is enlarged, distended and often tortuous veins of the abdominal wall with many anastomoses. The amount of the collateral circulation, involving the superficial veins of the abdominal wall, depends primarily upon the degree and duration of portal hypertension. Since in

Plate VI. Early cirrhosis of the liver. On the right is an infra-red photograph of the abdomen showing enlargement of the superficial veins with some anastomoses especially in the right upper quadrant. On the left is an ordinary film of the same case showing no demonstrable superficial veins.

satisfactory in our hands. Exposure time under these conditions is one second. The plates should be fresh and stored in an ice box or refrigerator, as they may become fogged by heat. For comparison we also photograph the abdomen using the orthochromatic plates without the filter.

The infra-red photograph of the abdominal wall in normal individuals shows a few narrow, straight, superficial veins in the groin and possibly over the lateral aspects of the abdomen. There are no demonstrable veins over the dome of the abdomen. On plate I, picture A is a representative infra-red photograph of a normal abdomen; for comparison, picture B is an ordinary photograph of the same case. In cases of increased intra-abdominal pressure due to large abdominal tumors, ascites or in advanced pregnancy, the veins of the abdominal wall are congested, dilated and more prominent. They become demonstrable by infra-red photography over the dome of the abdominal wall. Not infrequently they become visible on

portal cirrhosis of the liver the interference with the venous flow in the portal vein is of long duration and considerable degree, the veins of the abdominal wall are enlarged, tortuous and form numerous anastomoses, all of which can be demonstrated by infra-red photography. Dependent not only upon the duration of the disease, but also upon whether the portal circulation is compensated or not, the number of blood vessels and their anastomoses demonstrated by infra-red photography, varies from case to case. In well developed portal cirrhosis of the liver there is a large network of superficial abdominal veins on an infra-red photograph. Some of the larger ones may be visible to the naked eye or on ordinary photography. However, the true topography of these veins can be demonstrated by infra-red photography only. Plates IV and V show representative cases of advanced cirrhosis of the liver. One can see the numerous superficial veins and free anastomoses between them, while the accompanying ordinary photographs show none at all. Of greater

clinical importance is the demonstration of a similar but less marked network of superficial veins in early or doubtful portal cirrhosis of the liver. Such demonstration may clinch the diagnosis of cirrhosis in doubtful cases. Plate VI shows a representative case of this type. On the infra-red photograph one notices a considerable number of superficial veins, while the accompanying ordinary photograph reveals none. Furthermore, since portal cirrhosis of the liver is a progressive disease the graphic record of an infra-red photograph of the abdomen may be compared with a later one, which in this disease would show an increasing network of the superficial veins.

Cognisant of the fact, that the early diagnosis of portal cirrhosis of the liver is extremely difficult and at times impossible, we believe that infra-red photography offers a method of early diagnosis. On the other hand, the absence of an enlarged network of superficial veins of the abdominal wall does not rule out portal cirrhosis of the liver in the early stages. We feel, however, that in cases which appear as advanced cirrhosis, the absence of enlarged veins of the abdominal wall rules out this disease. In our experience,

metastatic carcinoma of the liver, diffuse abdominal carcinomatosis and gumma of the liver show no increase in superficial veins on infra-red photographs. This photographic demonstration can be used in differential diagnosis of portal cirrhosis of the liver.

SUMMARY AND CONCLUSIONS

Infra-red photography of the abdominal wall by visualization of the superficial veins of the abdomen presents a true pattern of these veins. This pattern varies in health and in abdominal disease. The pattern of the superficial veins of the abdomen in cirrhosis of the liver is pathognomonic of it. As such, it can be used to confirm a suspected case of this disease. However, the absence of the characteristic vein pattern does not rule out early portal cirrhosis of the liver.

The Efficiency of Several Germicides and Antiseptics on the Oral Mucosa*

By

ESTHER MEYER, PhG., M.S.

and

LYOYD ARNOLD, M.D.

CHICAGO, ILLINOIS

ACCORDING to observations made by Arnold and Stuart (1935), the lips apparently are a primary seeding zone for the mouth. The narrow zone of contact of the lips is an area which when inoculated with organisms, seems to furnish an unlimited supply for almost continuous contamination of the oral cavity.

It, therefore, was conceded that this zone would be a desirable one to make use of in order to test the efficiency of various germicidal solutions to be used on the oral mucous membrane. It was our aim to find an agent which would be the most efficient and whose action would continue for the longest period of time. The efficiency of germicidal agents on the skin has been reported in numerous papers. There have been, however, relatively few reports dealing with the direct application of a germicide to the oral mucous membrane.

Rodriguez (1928) published results of his experiments using the under side of the upper lip as the zone of application for the germicide. He used cotton rolls on both sides of the upper maxilla for a two fold purpose. It served as a dam against the outflow of Stenson's duct and prevented contact of the mucosa and teeth about the angles of the mouth. He used Mercurochrome 2% aqueous solution, Mercurochrome 5% in 50% alcohol, Mercurochrome 2% in alcohol, acetone mixture, Tincture of Iodine, and

glycerine 3.5%, and Tincture of Iodine and glycerine 1.75% and Iodine in alcohol 3.5%.

He concluded 3.5% Tincture of Iodine was too irritating on the oral mucosa but efficient. The 3.5% Iodine and glycerine mixture was effective and devoid of irritating effects. This solution has been used for a number of years in dental practice. The 1.75% Iodine and glycerine mixture is the lowest dilution which can be used and still be effective. Certain people, however, show some irritation upon using Iodine on the mucosa. Mercurochrome 5% in 50% alcohol was effective. It seems to have selective action for *Staphylococcus albus* but is irritating. The alcohol-acetone solution of Mercurochrome was too irritating.

In conclusion he states that Iodine is the most effective germicide to use on the oral mucosa in the presence of the organic elements constantly present on the surface of the mucous membrane of the mouth although he states that it was irritating to some people.

TECHNIQUE

The narrow zone of contact of the lips was numbered "zone 5". This zone was divided into four areas i. e., the left upper half was numbered area 1, the right upper half area 2, the lower left half area 3, and the lower right half area 4.

Sterile swabs were moistened with sterile normal saline solution and control swabs taken from zone five on areas 1, 2, 3, and 4. The swab was thoroughly rubbed over an agar plate streaking the plate across

*Department of Bacteriology and Public Health. University of Illinois College of Medicine, and the Department of Bacteriology, University of Illinois College of Pharmacy, Chicago.
Submitted February 7, 1935.

one way and then the other to insure as equal a distribution of the organisms as possible.

The average number of colonies obtained on control plates from zone 5, ranged from 600 to 10,000. As a matter of interest, zone 5 was cultured three times in succession, the average number of colonies on the first set was 1,550, the second set 2,280 and the third set 4,400. This experiment was repeated six times with the same result, that is, the second set showed a higher average than the first and the third set a higher average than the second.

In testing the germicidal solutions, a sterile swab was moistened with the agent and rubbed over the lips and zone 5. Then at intervals of 1, 3, 4 and 5 minutes, swabs were taken of zone 5 on area 1 in 1 minute, 2 in 3 minutes, 3 in 4 minutes, and 4 in 5 minutes and rubbed on agar plates as mentioned previously. In cases where the agent tested was found to reduce the bacterial count from 75-100% the duration in time of antiseptic action was determined.

A germicidal control plate was made in each experiment in order to ascertain whether or not any inhibition of growth was caused by the amount of germicidal agent taken up on the swab. A swab was taken from the lips immediately after the application of the agent and rubbed over an agar plate, then a drop of a liquid culture of *Staphylococcus albus* was spread on this plate. In no case regardless of the antiseptic used, was any inhibition of growth observed.

All plates prepared in this work were incubated for forty-eight hours and then counts were made using a Frost plate counter aided by a 9x hand lens. The total

number of colonies obtained from zone 5 both before and after the application of the antiseptic agent was determined and the percentage of reduction computed in this way. In testing of the germicides at least ten trials were made with each on as many different subjects as possible except in cases where the agent was found to be too irritating. The germicide found to be the most efficient and without too many objectionable qualities was tested twenty times on as many different subjects as possible. The following chart indicates the method used in computing the results:

CHART I			
Controls		Zone 5	Antiseptic Agent
Area 1	1,440	Area 1, 1 minute	50
Area 2	3,120	Area 2, 2 minutes	0
Area 3	2,880	Area 3, 3 minutes	35
Area 4	1,920	Area 4, 4 minutes	300
Total	9,360	Total	385
Percent reduction 95.9%			

Types of organisms cultured from Area 5 in order of frequency:

1. *Staphylococcus albus*.
2. Two types of minute colonies.
 - a. Larger ones consisting of either Gram positive diplococci, diphtheroids or Gram negative diplococci.
 - b. Minute pin point colonies which may be either streptococci, diplococci or diphtheroids. Some of the streptococci proved to be *Streptococcus lactis*, *Streptococcus salivarius*, others seemed to be dissociated forms. The growth of the dissociated forms is extremely

CHART II

Agents	Type of Solution	Average Reduction of Colonies in 5 Minutes	Duration of Action	Comments
Sod Perborate	30 grs in 4 oz warm water	85%	10 Minutes	More effective against staphylococci than streptococci
Hydrogen Peroxide	3% commercial solution	75%	10 Minutes	"
S T 37	Liquor Hexylresorcinolis 1 1000 solution	35%	—	In several subjects there was no reduction in count
1 Disodium salt of 2 7-dibromo-4-hydroxymercuriflorescen	2% aqueous solution	50%	—	Stain objectionable
	2% alcohol-acetone tincture	90%	30 Minutes	Solution too irritating, also stain objectionable
2 Sod salt of ethyl mercurithiosalicylic acid	1 100 alcohol acetone-aqueous monoethanol amine tinc	65%	—	Too irritating No reduction in count in several subjects
Neutral acriflavine.	1 1000 in normal saline	55%	—	
Phenyl mercuric nitrate	Sat aqueous solution (0.06%)	0%	—	Has a phenol coefficient of 625 and is non-toxic
Phenyl mercuric nitrate	Alcohol-acetone aqueous solution (0.034%)	50%	—	Too irritating
Glycerinated Iodine solution 3 5%	50% Tincture of Iodine, 50% glycerine	95%—* 100%	30 Minutes	Some subjects complained of irritation
"	25% Tincture of Iodine, 75% glycerine	75%	20 Minutes	"
Mineral Oil, Iodine solution 3 5%	50% Tincture of Iodine, 50% Mineral oil	95%—* 100%	40 Minutes	Longer action and less irritating Oiliness objectionable to some
Liquor Antisepticus	National Formulary VI	50%	—	
3 4 nitro 5-hydroxy-mercuri-ortho cresol	1 200 alcohol-acetone aqueous solution	95%—* 100% *	2 Hours	Only a very slight irritation to some No untoward after effects
"	1 500 Special Experimental mouthwash, Peppermint flavor	75%—* 85% *	1½ to 2 Hours	

* Cotton rolls used to restrict flow of saliva 1 Mercurochrome 2 Merthiolate 3 Metaphen

limited on media and growths in liquid cultures are difficult to keep alive.

3. Large wrinkled colonies, translucent in character and consisting of Gram negative diplococci and fours.
4. *Staphylococcus citreus* and *Staphylococcus aureus* occasionally.
5. *Subtilis* occasionally.
6. *Sarcina* occasionally.

It was observed with all of the germicides that there seemed to be more selective action against staphylococci than streptococci. In determining the duration of time which the germicides on the oral mucosa are effective, it was observed also that the staphylococci are inhibited for a longer period of time than the streptococci. The streptococci colonies appear in larger numbers sooner than the staphylococci colonies, returning suddenly and gradually increasing in number.

It was also observed that even in cases where some of the agents used were very effective, there would be an occasional individual whose tests indicated little or no antiseptic action had occurred on their oral

mucosa. This may have been due to the fact that some were not able to restrain the flow of saliva as well as others or as said by Hill and White (1930)—“We noted a variation in the ease of sterilization among different individuals. The skins of two laboratory technicians were not sterilized in either of two tests on each individual.” In the case of 4 nitro-5-hydroxy-mercuri-ortho cresol (Metaphen) however, we found this to be the minimum as compared to all other agents. Chart II shows the results obtained in the series of experiments.

CONCLUSIONS

The results of this study indicate that Tincture of 4-nitro-5 hydroxy-mercuri-ortho cresol (Metaphen-1 to 200) is the most effective agent both in its germicidal action on the oral mucous membrane and in the duration in time of antiseptic action. The tincture is convenient to use because there is little, if any, irritation, the color marks the area treated and it is very readily washed off with water.

Primary Carcinoma of the Liver*

By

ABEL LEVITT, M.D., F.A.C.P.

and

DEXTER S. LEVY, M.D.

BUFFALO, NEW YORK

THE dictum of Virchow which states that, “such tumors as are the frequent sites of secondary tumors rarely exhibit the primary type” seems particularly applicable to the liver. During the past ten years, in the wards of the Buffalo City Hospital, twenty-four cases were studied and diagnosed as primary carcinoma of the liver. Only twelve of these cases were proved by post-mortem examination and four by biopsy. We shall limit our discussion in this communication to the proven cases. In this same period of time 116,622 patients were admitted to the wards of the Buffalo City Hospital and in 2099 of these malignancy was diagnosed. Likewise, over this period of time about 4,400 autopsies were performed of which only twelve were primary carcinoma of the liver.

The statistical reports of White, Price and Leeds; Counsellor and McIndoe (1), would indicate that a comparatively small number of cases present this lesion. Our series bears this out and shows also that the disease occurs more frequently in the male sex, since we have observed fifteen males to one female. This fact is of interest in view of the striking contrast of sex incidence in carcinoma of the gall bladder, which is more common in the female. Likewise in metastatic carcinoma of the liver the incidence seems slightly higher in females.

Carcinoma of the liver, like most malignant diseases, occurs most often in the fourth to the sixth decade of life. Egge (2) reports the average age in his series as 57.2 years. We have observed the average age to be slightly lower, being 49.4 years.

It is apparent from the following table that the

*From the medical service of the Buffalo City Hospital and Department of Medicine, University of Buffalo. Submitted January 21, 1938.

greatest number of our cases occurred in the accepted age groups:

Age Groups	Number of Cases	Per Cent
30-35 years	2	12.5
35-40 years	0	0
40-45 years	2	12.5
45-50 years	4	24.8
50-55 years	2	12.5
55-60 years	2	12.5
60-65 years	3	18.6
65-70 years	1	6.25

The youngest case in our series was 34 years of age and the oldest 70 years. Prescott (3) reported a case of congenital carcinoma of the left lobe of the liver in an infant of five months, while Ribbert (4) reported a similar congenital malignancy in a four month old baby.

PATHOLOGY

A clinical classification of primary carcinoma of the liver which is frequently used includes:

A—*Primary, Massive Carcinoma* in which the cells are large and polyhedral and the liver attains a massive size. Only one case of our series was of this type.

B—Two of our cases were *primary infiltrating or diffuse* type.

C—Five conformed to the *nodular* or *multiple* types.

D—Eight cases in our series, seemingly developed in a cirrhotic liver, since elements of both were present.

Pathologically it would seem better to classify these tumors histogenetically. Primary carcinomata have only two sources of origin: (1) the parenchyma or liver cell and (2) the epithelial lining of the ducts. Mixtures of these two types have been observed, however. In the liver cell type, the lesions are usually multiple with a primary source but individual lesions are fairly sharply circumscribed. This type is very cellular and has little stroma, while umbilication and central necrosis occur early. A type of growth occasionally seen is that of a huge liver with decided increase of connective tissue, suggesting an exaggerated proliferation of the bile ducts, which crowd the lobular structure to the point of atrophic disappearance. This type has been termed Banti's Disease when associated with splenomegaly, and in previous years, was also referred to as "Cirrhosis carcinomatosis."

CLINICAL FEATURES

The clinical manifestations in our cases were quite variable. Pain was a rather constant feature, being present in eleven of the group and located either in the epigastrium or the right upper quadrant of the abdomen. Anorexia and emaciation was present in all instances, but pronounced in only six of the entire group. Jaundice was rather infrequent and occurred in six

cases, while subclinical jaundice was present in an additional four. Nausea, emesis and constipation were infrequent symptoms. The liver was definitely enlarged to palpation in every case and was nodular in more than half of them. The spleen was palpable in only four cases of the entire group. Ascites occurred in six cases; the fluid removed from the abdominal cavity was exudative in character, and tumor cells were recovered from the centrifuged sediment in three different cases.

LABORATORY FINDINGS

There has been some reference (5) to the presence of fever and leucocytosis in the latter stages of this malady. In six or thirty-six and a half per cent of our cases leucocytosis was present. In no case did it go above 20,000 cells and in the majority of cases, it varied between 10,000 and 14,000. Fever was observed throughout the course of the disease in only six cases, but was present terminally in an additional six. The blood urea N was normal in our entire group; in none was it higher than 20 mm. per 100 cc. of blood. The Wassermann reaction was positive in only two of our cases. The blood sugar was within normal limits in all instances.

COURSE

The course of the disease in our group was rapid and fatal. The majority of our patients presented distinct clinical manifestations of the disease within one year of their initial complaint. More than half of the group, however, had symptoms for less than six months. Thirteen of this group were observed in the hospital less than six weeks prior to their death, indicating the rapidity of this disease.

METASTASIS

Metastasis from the primary liver focus occurred usually by way of the regional lymph glands, but extra hepatic metastases have been found in about twenty per cent of cases reported in the literature (5). Our findings agreed with this, for we found that fifty per cent of our cases showed metastasis in the regional lymph nodes, while in one instance each, there was metastasis to the pericardium, lung and mesentery.

SUMMARY

We have reviewed sixteen cases of primary carcinoma of the liver diagnosed clinically and confirmed pathologically. We have also briefly presented the clinical manifestations of this disease.

The Use of Hydrated Magnesium Trisilicate in Peptic Ulcer*†

(Preliminary Report)

By

MANFRED KRAEMER, M.D., F.A.C.P.‡
NEWARK, NEW JERSEY

HYDRATED Magnesium Trisilicate was introduced into therapeutics in 1936 by N. Mutch (1, 2, 3). The first to write about the subject in the American literature was Levin (4). He used the trisilicate of Magnesium in a mixture with other antacids to treat peptic ulceration. Hurst (5) is the only other author who has referred to the clinical use of this substance.

Because, according to Mutch, the antacid power of Hydrated Magnesium Trisilicate is sustained for hours even in the presence of excess of acid, because its adsorptive power lasts even for a few days, because it has strong antipeptic powers, because even in large doses it causes neither constipation nor diarrhea, and because it cannot produce alkalosis by absorption of unused excess, I considered this an ideal antacid for use in patients with peptic ulcer. All antacid powders have certain definite drawbacks—the constipation caused by Bismuth and Calcium Salts, the laxation of Magnesia, the secondary rise and tendency to alkalosis caused by Sodium Bicarbonate are well known. For the past two years I have used Colloidal Aluminum Hydroxide preparations with good results and without some of the ill effects expressed above except for very frequent complaints of constipation and two cases of fecal impaction.

In view of the marked relief of symptoms obtained in peptic ulceration with the use of Magnesium Trisilicate I am presenting this preliminary report to stimulate further clinical trial of the powder. My results have been so gratifying that I am replacing other alkalis with this preparation.

I have now used Hydrated Magnesium Trisilicate in 38 private patients having roentgenologically proven duodenal ulcers associated with definite hyperacidity to a test meal, and typical symptoms. The preparation has also been used on several clinic patients fulfilling the same criteria. Due to insufficient time for follow up on the clinic cases I am not including them in this preliminary report. The drug has been used by the patients for from three to six months. The patients were all kept on an ambulant diet. A few had a preliminary rest period at home of from three days to two weeks. In general the routine was the same as I have used for some time except for the substitution of the Hydrated Magnesium Trisilicate in place of other

antacids. The patients received three light meals per day and a glass of milk or milkshake or tea between meals and in the evening. One hour after meals and one hour after the between meal feedings and at bedtime they were given a teaspoonful of the powder. Some bromide or phenobarbital was given if there was excessive nervousness or sleeplessness. Some of the patients also received tincture of belladonna. If there was night pain the patients set their alarm clocks one hour before the anticipated period of distress and took a teaspoonful of the powder at that time. Some of the patients had had ulcer symptom recurrences for many years and had had many types of treatment. Two of the patients had had a gastro-enterostomy for ulcer with recurrence of symptoms but without demonstrable jejunal ulcer. One had been doing well on Colloidal Aluminum Hydroxide but complained of constipation. On changing to the Magnesium Trisilicate he continued to do well and no longer was constipated.

All the patients in this group are improved. Of course, this is the usual response to any new therapy. However, to control psychic factors, the patients were not told that they were receiving a new preparation. I do not hold Magnesium Trisilicate to be a cure for peptic ulceration but merely as a valuable antacid. Antacids are used not to cure ulcers but to control symptoms. The cure of ulcer is a problem of changing the patient's mode of living, thought process and dietary habits so that the factors producing recurrences will not come into play. Of prime significance in the use of this powder is the fact that not a single patient complained that it affected his bowel habits in any way. None of the patients showed symptoms of alkalosis. Hurst (5) has given this preparation in 30 grain doses to ulcer patients and alkalosis has never developed.

I am not presenting a statistical table in this preliminary report. The time the patients have been under treatment is too short and the number of cases is too few for use of any statistical method of evaluating the powder. In my clinical judgment, this is a valuable therapeutic agent which merits further trial.

Variations in the Level of Serum Lipase in Experimental Pancreatitis*

By

HAMILTON BAXTER, M.D.,
STEWART G. BAXTER, M.D.

and

JOHN F. McINTOSH, M.D.
MONTREAL, CANADA

BIOCHEMICAL methods available for the study of acute pancreatitis depend for the most part on a study of the distribution of the pancreatic enzymes in the body. In general, these methods have not proved themselves to be specific, nor serviceable in indicating the severity or the course of the pathological lesion. Cherry and Crandall (3) have introduced a method for determining the amount of olive oil splitting lipase in the blood as a means of studying the reaction of the pancreas to experimental procedures. This method has not been hitherto used in the study of the level of serum lipase in experimental pancreatitis.

Claude Bernard in 1856 produced acute haemorrhagic pancreatitis in the dog by injecting bile and sweet oil into the pancreatic duct. Since then many other substances have been used to cause experimental pancreatitis (10, 8, 13, 14, 5, 12). Archibald (1) in experiments on the cat has caused pancreatitis of varying degrees of severity by running bile into the gall bladder, the sphincter of Oddi being contracted by various means and also by inserting a cannula into the pancreatic duct through the ampulla of Vater and running normal and infected bile into the pancreatic duct at a pressure similar to that normally present in the biliary passages.

The pathological findings were recorded by both gross and microscopic examination at various periods after operation. It was found that all grades of pancreatitis from simple oedema to acute haemorrhagic pancreatitis with necrosis could be produced. Chiray, Berdet and Taschner (4) using both a stalagmometric method with tributyrin as a substrate and also a titration method with an olive oil substrate sometimes found lipase normally present in the blood serum of the dog and its amount was increased by the injection of secretin and pilocarpine. Fiessinger, Fernet and Gajdas (7) also using a stalagmometric method with tributyrin as a substrate found more lipase normally present in the blood of the dog than in man and they noted almost as much lipase in the blood of depancreatized dogs up to two weeks after operation. Cherry and Crandall (3) using a modification of the Loevenhart (11) method for esterase with an olive oil emulsion as substrate have shown that following ligation of the pancreatic ducts, division of the pancreas between ligatures and excision of the body of the pancreas, an olive oil splitting lipase appeared in the blood in large quantities while there was no significant uniform change in the amount of serum esterase as measured by the hydrolysis of ethyl butyrate or tribu-

tyrin. They believe that the rapid rise of an olive oil splitting lipase in the blood following pancreatic obstruction, without a corresponding increase in the serum esterase to be good evidence of the specificity of pancreatic lipase. They have also shown that tributyrin hydrolysis is not an index of the presence of true pancreatic lipase and they concluded that the conflicting results of many investigators who used tributyrin and ethyl butyrate as a substrate may be explained by their findings. Several authors (15, 4, 3) have suggested that the term lipase should be reserved for the enzyme acting on the triglycerides of the higher fatty acids while esterases may be defined by their property of hydrolysing the simple esters or mono-esters.

Baló and Ballon (2) have studied the effect on the pancreas of acute and chronic obstruction of the pancreatic ducts. They found that retention of the pancreatic juice caused dilatation of the ducts and acini, with flattening of the acinar cells, and that necrosis might follow.

The purpose of our experiments was to produce a pancreatitis by injecting bile into the pancreatic duct and to follow the change in the level of serum lipase and to see if any relation existed between the height of the blood lipase and the degree of pancreatitis. The duct was not ligated and the pancreatic secretion was permitted to resume its normal flow into the duodenum once the inflammatory reaction had subsided. In this way the back pressure effects on the gland observed by Baló and Ballon were avoided. This procedure simulated more closely the mechanism of production of pancreatitis in man as postulated by Archibald.

METHOD

In these experiments seven dogs were used. They were fed a diet of Purina dog biscuit and as much water as desired. The blood was collected in the fasting state. The method of Cherry and Crandall (3) for determining lipase was used. To 1 cc. of serum were added 2 cc. of a fifty per cent olive oil emulsion* and 0.5 cc. of N/3 potassium phosphate buffer adjusted to pH 7.0. This was then incubated at 37° C. for 24 hours. Then 3.0 cc. of 95% alcohol were added and 3 drops of 1 per cent phenolphthalein. Titration was performed with N/20 sodium hydroxide and the result was expressed in cc. of N/20 sodium hydroxide per 1 cc. of blood serum. The determinations were made in duplicate and control blanks were titrated with each group of determinations. At operation, the main pancreatic duct was located, a fine needle was inserted into its lumen and depending on the size of the dog from two to five cc. of bile aspirated from its gall

Chart No. 1 shows the course of the serum lipase following injection of normal bile into the major pancreatic duct. From 2-5 cc. of bile were injected.

bladder were injected slowly with a syringe. Immediately following this procedure the pancreas became stained with bile which in most cases penetrated the finer ramifications of the ducts as far as the tail. The surface of the gland became glassy from oedema of the pancreas. Within two or three days all the dogs seemed to have recovered from the shock of the operation.

Chart 1 shows the effect on the level of serum lipase following injection of bile into the duct of Wirsung. In every case a high level had been reached in twenty-four hours and in one dog as early as the sixth hour post-operatively. The amount of lipase was from fifteen to fifty times that of the pre-operative value, which in the dog is very low. After attaining a maximum in from 24 to 48 hours the lipase declined abruptly at first and then more gradually until after 7 to 10 days it had almost returned to normal. Since the pancreatic duct was only slightly traumatized there was nothing to prevent the external pancreatic secretion from resuming its flow into the duodenum once the inflammatory reaction had subsided. The dogs were sacrificed at periods varying from three days to twelve weeks after operation and sections were taken from the head, body and tail of the pancreas for microscopic examination.

PROTOCOLS

Dog No. 7. Weight 16 kilos. Under avertin anaesthesia 4 cc. of bile were injected into the major pancreatic duct. The pancreas became stained with bile throughout and the gland was slightly swollen before the abdomen was closed. Three days later the dog was again anaesthetized and the abdomen was reopened. On gross examination the omentum was found to be adherent to the pancreas and there were many areas of fat necrosis in the vicinity of the pancreas and duodenum. The pancreas was swollen and firm and a small abscess was found in the body. The pancreatic duct was examined and found to be patent. Microscopic sections showed a marked interlobular inflammatory exudate with evidence of fibroblastic proliferation. There were patchy areas of necrosis of the parenchymal cells, between which the acinar cells were relatively well preserved though the lobules were

separated by inflammatory exudate. This dog showed the pathological picture of acute haemorrhagic pancreatitis with necrosis. The course of the blood lipase is indicated in Chart 1, and Photomicrograph No. 1 shows a typical section taken from the pancreas.

Dog No. 6. Weight 20 kilos. Intravenous injection of avertin was used to produce anaesthesia. The duct of Wirsung was located and 4 cc. of bile were injected into it with the result that the pancreas was tinged with bile throughout its whole extent. Eleven days later the dog was killed with ether. On opening the abdomen a few adhesions were found between the omentum and duodenum. The pancreas seemed to be normal in appearance on gross examination. No areas of fat necrosis were seen. On microscopic examination sections taken from the head, body and tail of the pancreas showed a slight increase in fibrous connective tissue in focal areas about the ducts and in the interlobular stroma. The tail showed areas of round cell infiltration. The highest value for serum lipase was 2.80 cc. reached three days after operation.

Dog No. 1. Weight 22 kilos. After induction of anaesthesia with avertin, 4 cc. of bile were injected into the major pancreatic duct. The whole pancreas became stained yellowish with bile and before the abdomen was closed the gland was swollen and glassy from oedema. Thirty-eight days later the abdomen was reopened. A few adhesions and some small areas of fat necrosis were noted in the vicinity of the tail of

Photomicrograph No. 1. The section from the body of the pancreas of dog No. 7 shows a marked interlobular and intralobular inflammatory exudate with evidence of fibroblastic proliferation. Areas of necrosis of the acinar cells may be noted.

Photomicrograph No. 2. The section from the tail of the pancreas of dog No. 1 shows a focal area of parenchymal cells undergoing replacement with fibrous connective tissue.

the pancreas. Two cc. of bile were injected into the pancreatic duct and the abdomen was closed. Forty-seven days later the dog was sacrificed with ether. On gross examination the pancreas appeared normal. Microscopic sections showed focal areas of fibroblastic proliferation about the ducts and in the interlobular tissue. Chart 1 shows the course of the serum lipase. Photomicrograph No. 2.

Dogs No. 3 and No. 5 were sacrificed thirty-five and sixteen days, respectively, after operation and microscopic examination showed only focal areas of fibrous connective tissue about the ducts and in the interlobular stroma. Dogs No. 2 and No. 4 who came to autopsy eighty-four and thirty-one days, respectively, after operation showed no definite change in the pancreas. In no case did the pancreatic ducts appear to be dilated.

DISCUSSION AND SUMMARY

Following the injection of bile into the major pancreatic duct there was a prompt rise in the serum

lipase which usually reached a maximum in twenty-four to forty-eight hours. After reaching a peak it subsided abruptly at first and then more gradually until an approximately normal level was reached within seven to ten days post-operatively. The changes found at autopsy varied from a typical acute haemorrhagic pancreatitis with necrosis to a reaction so slight that eleven days after injection of bile into the duct of Wirsung the only changes noted in the pancreas were focal areas of fibrosis and round cell infiltration. In two dogs which showed a high level of blood lipase following operation no significant changes were found in the pancreas at necropsy.

It would appear that different degrees of pancreatitis were produced in the various dogs by injecting bile into the major pancreatic duct. Possibly as McCaughan (11) has suggested, the more severe grades of pancreatitis may be caused by rupture of some of the finer ducts and extravasation of the bile into the parenchymal substance. Undoubtedly other factors exist which may modify the intensity of the inflammatory reaction. For example, the greater the amount of mucin in the bile the less severe is the pancreatitis caused by its injection into the pancreatic duct (9). The rise in the amount of serum lipase in most cases is probably dependent on the amount of oedema or inflammatory reaction produced by the injection of bile.

In dog No. 6 at necropsy, the pancreas showed a relatively slight degree of pathological change though the serum lipase reached a fairly high level after operation. In this dog the inflammatory reaction was probably quite mild and oedema with temporary occlusion of the pancreatic ducts may have accounted for the increased serum lipase.

On the other hand, in the more severe grades of pancreatitis the serum lipase may not rise as high as in the milder inflammatory reactions due to extensive destruction of the acinar cells or obstruction of the blood or lymph vessels. Confirmation of this fact was seen in one patient who was admitted to the hospital with signs and symptoms suggestive of an acute upper abdominal condition. The blood lipase was normal. At operation a hyperacute pancreatitis was found. At autopsy focal areas of necrosis were found throughout the pancreas with marked collapse of the acinar cells. Comfort (6) in a series of twenty-one cases of acute pancreatitis noted one patient in which the serum lipase remained at a normal level.

Increased serum lipase occurs regularly in experimental pancreatitis and its estimation should prove a valuable diagnostic aid to the surgeon in cases showing signs and symptoms suggestive of acute or sub-acute pancreatitis.

The authors wish to acknowledge their indebtedness to Dr. T. R. Waugh and Dr. W. H. Chase for the preparation and interpretation of the histological slides.

Cod Liver Oil Per Rectum as an Adjunct in the Treatment of Ulcerative Colitis*

By

R. RUSSELL BEST, M.D.†
OMAHA, NEBRASKA

PATIENTS with ulcerative colitis not infrequently show marked symptomatic improvement under treatment—may, in fact, appear symptom-free—yet proctoscopic examination reveals that the mucosa of the rectum lacks sufficient healing power to arrive at complete regeneration or firm scar formation. Again, the process of healing may produce such a pronounced cicatricial formation that the rectum resembles a rigid fibrous tube. Some patients seem to lack the ability to respond either by symptomatic improvement or by local improvement of the rectal or colon wall. Such incidents are fully appreciated only by those who make visual examination of the rectum and lower sigmoid.

It is not the purpose of this paper to present a specific for the treatment of ulcerative colitis, but rather to present a measure which at times serves as a valuable adjunct to other forms of therapeutics. Two years' experience with cod liver oil has revealed some interesting findings. It is offered as an entirely new idea with some hesitation, for further scanning of the literature might reveal a suggestion or clinical report of its use. Up to the present, however, no such reference has been found.

Those of us who are more surgically minded about colon lesions realize that the immediate mortality in surgery of the colon for ulcerative colitis is high and that the later mortality is great enough to inspire search for a satisfactory non-operative method of treatment.

Since we have not arrived at definite conclusions regarding the etiology, we must apply those therapeutic measures which logic and experience have proved are valuable. Individualization of treatment and using the various methods of treatment with resourcefulness and good clinical judgment have accounted for those results which were successful.

An article by Lohr in 1934 on the local treatment of fresh wounds and burns with cod liver oil salve aroused considerable interest, and the use of cod liver oil per rectum seemed to the author to be worthy of careful clinical trial in ulcerative colitis. Lohr demonstrated that cod liver oil causes liquefaction of necrotic tissue, that it has a strikingly inhibiting effect on the bacterial flora of wounds and that it is a powerful stimulant of growth affecting all tissues. He is of the opinion that these effects are due to vitamins A and D.

Lohr also reported that ordinary streptococci, staphylococci and *B. coli* usually perish when placed in cod liver oil, probably from a lack of nourishment or from the surface tension of the oil. Lost and Kochergin report on 263 cases of ulcerated wounds treated with cod liver oil paste and believe their excellent results are

due to an abundance of the vitamins A. and D. They express the opinion that there is a lack of vitamins in pathologic lesions either because of an interrupted supply or an increased demand. As one considers the sequence of events in ulcerative colitis, this seems particularly applicable for the abnormal activity of the intestinal tract may inhibit proper absorption of the vitamins. Lost and Kochergin also state that cod liver oil lowers the vitality of pus-producing bacteria. Tumanskiy and Yatsevich found that the growth of streptococci ceases after one hour in both sterile and non-sterile cod liver oil and that staphylococci live but six hours. Hayashi concurs that the healing power of cod liver oil is due mainly to the effects of vitamins A and D and to the lipoids contained in the oil. It is generally agreed by most observers that vitamin A promotes tissue formation and that it is a physiologic prophylactic against infection by virtue of the fact that it maintains the health and integrity of the epithelial lining of the mucous tracts and skin. Vitamin D controls calcium equilibrium and regulates mineral metabolism. The report of the favorable use of calcium and parathyroid in ulcerative colitis by Haskel and Cantarow denotes the possible therapeutic value of vitamin D.

With these points in mind, it was felt that the application of cod liver oil directly to the diseased area in ulcerative colitis, rather than diluting it by passage through the stomach and intestines, was worthy of investigation. In order to better evaluate this treatment, it was first used on patients who had not responded satisfactorily to the various accepted therapeutic measures. These first three patients had been subjected to all known methods of treatment, yet they appeared to be fast approaching that stage where surgical intervention would be necessary. Two of them were still in the hospital and the third had been home but for a short time, and all energetic methods of treatment had been abandoned. They were merely on low-residue high-vitamin high-calorie diets, hot abdominal packs and paregoric and bismuth by mouth. Without otherwise changing the treatment, 4 ounces of cod liver oil were instilled into the rectum each day after a normal saline enema. After three weeks, the patients had not improved either symptomatically or in proctoscopic appearance. In view of the fact that slight temporary improvement had at times followed the routine use of yalren, acriflavine and gentian violet, it was decided to institute another such course of treatment and follow it immediately with cod liver oil rectal instillations.

Our experience with acriflavine has been similar to that of Crohn and Rosenak who reported in 1936 that of 75 cases treated, 44.5% were cured and 29.9% improved after a 2 to 4 year follow-up period. We have

Submitted January 20, 1938.

usually preceded acriflavine with yatren, however, and followed it with gentian violet for yatren is valuable in controlling any possible associated amebic infection, as well as for its general antiseptic qualities, while the selection of certain bacteria by acriflavine and of another group by gentian violet satisfies the hope that these drugs might be beneficial.

The method of treatment was as follows. Each drug was given by mouth and through rectal instillations for a period of five days. Yatren was used first, one tablet by mouth three times a day and at bedtime, with daily rectal instillations of 8 ounces of 1% solution, following a normal saline enema. This was followed with acriflavine, $\frac{1}{2}$ grain tablet three times daily and at bedtime, and instillations of 8 ounces of 1:5000 solution. The third period, gentian violet was given in the same manner as the acriflavine. As before, all these patients showed some improvement. Daily rectal instillations of 4 ounces of cod liver oil were begun immediately after the gentian violet treatments. Two patients improved markedly in three weeks, both symptomatically and by change in the appearance of the rectal mucosa, but because one was not making as rapid progress as the other, he was given a second course of the entire treatment. The third patient responded slowly, and was given three courses of the drugs, followed each time by three weeks of cod liver oil.

In each instance the bowel activity was reduced to four or five stools a day, the stools were more formed and were not accompanied by bleeding. The remarkable feature, however, was that immediately after starting the cod liver oil instillation, the ulcerated mucosa had a cleaner appearance, the necrotic grayish spots disappeared, and the granulating areas became bright red, with definite evidence of active epithelialization. The softer appearance of the bowel wall was unmistakable, the scarring did not produce as pronounced a contraction, and the epithelialization was smoother and more normal than that observed in previous ulcerative colitis cases. Of these three patients, two have remained symptom-free, with a quite natural appearing rectal mucosa, for 22 and 21 months respectively. The third patient, who did not respond so readily, has remained symptom-free except on two occasions when he contracted a little cold, which caused a mild flare-up of his symptoms. He has always responded quickly to a repetition of the treatment. X-rays reveal some rigidity of the colon in each case yet there is definite improvement over previous studies.

Fourteen other cases of ulcerative colitis have since been treated in a similar manner. None of these were of such a severe nature as the three mentioned above and only two had not received some form of treatment previously. These two have remained symptom-free for 8 and 14 months respectively, having no more than five stools daily and these of fairly formed consistency and not accompanied by bleeding. They are in good physical condition and are holding down positions. The other twelve victims had all had frequent recurrences of symptoms but had responded to various forms of therapy. Each was given one course of treatment with the dyes, followed by three to six weeks of cod liver oil instillations. It was deemed advisable to repeat one or more of the drugs occasionally, and for most of them the amount of cod liver

was reduced to 2 ounces. At times after two weeks of cod liver oil instillations, the oil was given only on alternate nights. Eleven of these patients showed more rapid symptomatic response, the mucous membranes appeared smoother and the intestinal wall less rigid than under previous treatment. The twelfth patient improved under the regime at first but after six weeks, it was concluded that no further benefit could be derived, although the mucosal wall did appear cleaner and healthier. Another form of treatment was instituted and recovery promptly followed.

Of these twelve patients, only three have had relapses severe enough to necessitate repetition of the entire course of treatment and the response has been most satisfactory in each instance. At the present time, the other nine have remained in excellent condition for periods of three to twenty months.

In but one instance did the cod liver oil act as an irritant and it was promptly discontinued. However, this patient, although she had formerly had frequent relapses, has not had a return of her symptoms in eight months following the cod liver oil instillations and has never felt as fully recovered. The rectal mucosa looks almost normal except for some excess mucus and a few hemorrhagic areas.

In two other cases, all symptoms have disappeared, yet the mucosa has not entirely healed, although it more nearly approaches normal than during previous remissions. Both have remained symptomatically well for some ten months.

The detailed technic of administering cod liver oil per rectum is as follows: An enema of one pint of normal saline is given first, and after this is expelled, two to four ounces of the oil are instilled with an all rubber rectal syringe while the patient is in the knee-chest position. This position is maintained for three to five minutes and the oil retained as long as possible.

Some vegetable mucin product or Kaomin is of value in obtaining better formed stools, as formed stools seem to have a beneficial psychic effect upon these patients. Since using cod liver oil as an adjunct in our treatment, we have had less difficulty in bringing patients to the stage where they have one or more formed stools each day. During the more active phase of the disease, a mixture of equal parts of paregoric and milk of bismuth is prescribed, two drams after each second bowel movement. The usual dietary restrictions and general supportative and symptomatic measures are mandatory.

SUMMARY

1. Cod liver oil instilled into the rectum is a definite aid to the healing of ulcerative colitis lesions.
2. It seems to be valuable merely as an adjunct and of no value if used alone.
3. Daily instillations of from two to four ounces have been used following a course of treatment with yatren, acriflavine and gentian violet.
4. Of seventeen cases treated, thirteen (76%) have remained practically symptom-free for periods varying from three to twenty-two months. Only two showed marked residual ulceration while being otherwise symptom-free. Several showed incomplete healing of a minor degree.
5. The chief value of the cod liver oil seems to be that it produces a cleaner, more pliable and healthier appearing bowel wall with less dense scar formation.

The Relationship of the Diet to the Self-Regulatory Defense Mechanism

I. Hydrogen-Ion Concentration and Bacterial Flora

By

NICHOLAS P. SULLIVAN, M.S.

and

IRA A. MANVILLE, M.D., Ph.D.*

PORTLAND, OREGON

INTRODUCTION

THE use of fresh fruit as premeals and as additions to the basal diet have been shown by many workers to influence the hydrogen-ion concentration, bacterial flora and the auto-regulatory defense mechanism of the gastro-intestinal tract. The variation encountered in fresh fruits gathered from different localities, and the still greater differences in fruits of different varieties and age prompted us to use a dehydrated apple powder of known composition.

Many factors have been suggested as the reason for the beneficial results obtained by the use of fresh fruit diets. Among these are the hydrogen-ion concentration and the carbohydrate (organic acids, cellulose, hemicellulose, lignin) content of the fruit. In dealing with the pH one must consider that a great variety of organic acids may be present in the fruit itself. Furthermore, other acids may be produced in the intestine by the action of body enzymes and of intestinal bacteria on carbohydrates, chief of which are lactic, acetic and butyric acids. Moreover some of these acids, aside from their effect on pH, may be toxic to certain organisms, thus preventing the development of a flora unfavorable to the host.

The experiments reported herein were performed in an effort to evaluate these factors and their relationship to the self-regulatory defense mechanism of the gastro-intestinal tract. By "the self-regulatory defense mechanism" we refer to the concept as developed by Arnold and his co-workers (1). Dehydrated apple was used in feeding because its stable composition allowed exact duplication of experiments. The data covers work done in determining the effect of the experimental diet on the fecal pH and the bacterial flora. Special attention was given to the study of the cellulose-splitting organisms since it has been shown that these bacteria produce organic acids. In experiments already reported (2), we studied the effect of vitamin A deficiency and uronic acid depletion in relationship to the lysozyme content of tissues and secretions. Our studies on the effect in vitro of various organic acid and pectin on intestinal organisms will appear in a subsequent report.

HISTORICAL

Bienstock (3) found that the upper half of the small intestine of laboratory animals as compared with the lower half was comparatively free of bacteria. Gessner (4) drew similar conclusions in his work with the human gastro-intestinal tract. To test the auto-sterilization mechanism, Schuetz (5) introduced B.

*From The Nutrition Research Laboratory, Department of Medicine, University of Oregon Medical School, Portland, Oregon. Submitted February 7, 1938.

Plate 1. Veillon Tubes Cultures. I. Typical culture from cecum of pellet fed group showing 4 plus gas production. II. Typical culture from cecum of pellet plus apple powder fed group showing no gas production.

metschnikovi into the duodenum of dogs and found that the organisms were killed before reaching the ileum. Rolly and Liebermeister (6) substantiated Schuetz's findings, using *B. pyocyaneus* in rabbits. Van der Ries (7) concluded from his observations that the defense mechanism is one of auto-disinfection and not of auto-sterilization. Arnold (8, 9) investigated the effect of diet and meteorological changes on the endogenous enteric bacterial flora and the permeability of the intestinal wall. He found that in dogs, after the ingestion of an alkalinized food, a high-protein meal or

during the period of adjustment to a high external temperature or fever, there was a decided interference of the bacteriostatic power of the small intestine. In the small intestine, the interference with the bacteriostatic action on exogenous bacteria is accompanied by a marked disturbance in the regulation of the endogenous bacterial flora. The duodenum and upper part of the jejunum were the last to lose this auto-disinfecting power. The sudden alkalinization of the upper part of the small intestine and the presence of protein material or bile allows bacteria to pass through the wall of the intestinal tract and appear for a short period in the thoracic duct. Puppies kept in a hot room and fed *B. prodigiosus* in milk showed viable organisms in their stomachs. However, if the milk were acidified, no organisms were recovered.

Nedzel, Stonecipher and Arnold (10) administered saponin to dogs and studied the intestinal changes in the distribution of *Esch. coli* and in the hydrogen-ion concentration. Their results show that the oral ingestion of saponin caused a sudden change in the acid-base equilibrium and in the endogenous flora. This was associated with the appearance of viable *Esch. coli* in the organs of the animal. As the hydrogen-ion concentration increased, there was a decrease in viable *Esch. coli* in both the intestinal contents and in the organs. Nedzel and Arnold (11) and Johnson and Arnold (12) found that exogenous bacteria (*Esch. coli*) when introduced into the stomach in the presence of free hydrochloric acid lose their viability. When the gastric contents were alkalinized with a phosphate buffer solution, previously non-viable exogenous bacteria regained their viability. As the pH of the gastric contents increased there was a parallel increase in the viable exogenous organisms.

The above experiments were further extended by Johnson and Arnold (12). The test bacteria were suspended in saline, milk, phosphate buffer solutions and meat. At the beginning of the experiment there was an acid deficit which persisted for one hour. During this deficit, there were 150,000 bacteria per cubic centimeter. As soon as free acid was detected, no viable bacteria could be demonstrated. When alkaline phosphate solution was introduced to neutralize the free acid, viable organisms reappeared and persisted during the period of the acid deficit. They also found that if the gastric contents were removed when there was free acid present and then neutralized, no viable bacteria could be demonstrated.

Seidmon and Arnold (13) using rats as experimental animals, investigated the intestinal acid-base equilibrium and distribution of the bacterial flora on vitamin A and B deficient diets. The vitamin deficient rats were found to have a denser intestinal bacterial population and a more alkaline pH than the normal.

Recently a number of investigators have reported the use of fresh or dehydrated fruit either as a meal or as a premeal as a means of controlling the acid-base equilibrium in the intestine. Arnold (1), Bergeim, Hanzen and Arnold (14) and Esselen (15) using such fruits as apple, banana, cranberry, prunes etc. found that such diets tended to raise the hydrogen-ion concentration of the intestinal tract. With this rise, there was a decrease in viable *Esch. coli*.

EXPERIMENTAL

All of the rabbits used in this experiment were fed a basal diet of pellets containing ground oats, alfalfa

meal, ground barley, wheat germ meal, molasses, linseed oil meal, whole milk flakes, cod liver oil, ground wheat, soy-bean meal, brown malt, sprouts and minerals. Two experimental groups of animals were used.

tained finally that produced a tough membrane suitable for use. These membranes were treated with dilute NaOH to remove bacterial proteins. These membranes were then immersed in dilute HCl to remove

both receiving the basal pellet diet. In addition one group received dehydrated apple (30 grams per animal per day). The animals were kept on these diets until all showed a substantial gain in weight. Growth curves of both groups were essentially the same. The animals were then sacrificed by a blow and the gastro-intestinal tract removed. The contents of five levels of the intestine, namely, the duodenum, jejunum, ileum, cecum and colon, were removed under aseptic conditions.

Nutrient agar and Endo's agar were inoculated from serial dilutions of the intestinal contents. From these plates, further identifications were made. Veillon tubes containing whey agar were also inoculated. After forty-eight hours incubation, these tubes were examined for gas production. Cultures for the determination of cellulose-splitting organisms were made on a modification of the media recently described by Aschner (16). The media described by Aschner is composed of membranes produced by the growth of *Acetobacter xylinum*. Cultures of *Acetobacter xylinum* were obtained from the American Type Culture Collection and from Dr. Aschner,* but suitable membranes from these cultures could not be grown. Cultures were made from material obtained from various stages in the manufacture of vinegar. One was ob-

tained finally that produced a tough membrane suitable for use. These membranes were treated with dilute NaOH to remove bacterial proteins. These membranes were then immersed in dilute HCl to remove

the alkali and then washed until free of acid. Aschner advised the use of wide mouthed bottles for the growth of these membranes. It was found, however, that the membranes could be grown more satisfactorily in petri dishes, thus providing membrane discs of the proper size. It was found further that Brewer's yeast could be substituted for marmite in the *Acetobacter xylinum* media and that maltose (three per cent) seemed to aid materially in the growth of these membranes.

Using the modified Aschner media, serial dilutions of the contents of the various intestinal levels were cultured. These cultures were made in duplicate and incubated under both aerobic and anaerobic conditions. The pH determinations of the five intestinal levels were made with a glass electrode pH meter. Direct smears were made of each level and stained by Grams method. Table I shows the hydrogen-ion concentration at the various levels. As will be noted the group receiving dehydrated apple showed a higher hydrogen-ion concentration in all five levels.

The greatest difference in pH was found in the ileum and the greatest hydrogen-ion concentration in the cecum. The pH values of the group receiving apple supplement showed a steady decrease in the small intestine. Just the opposite prevailed in the pellet-fed group. In both groups, the cecal pH was acid but in

*We wish to acknowledge with thanks the kindness of Dr. Aschner in providing us with a culture of the organism with which he worked.

the former the acidity was almost ten times that of the latter. In the colon the pH tended to rise. In the pellet-fed group the pH changed to an alkaline one and equaled that found in the duodenum. The group getting the apple supplement still retained an acid re-

increase in the growth of cellulose splitting organisms in the rabbit—an herbivorous animal—it was thought that the rat might prove more suitable for demonstrating this point.

Two groups of rats were used. Both groups received

Aver.	19.3	57	23.7	0	22	53.1	24.9	0

action which was equal to that found in the jejunum. Cultures taken at these levels showed that the group receiving dehydrated apple developed an aciduric type of flora and that the Esch. coli were greatly decreased (Table II, a and b). Also the Veillon whey agar tubes gave gas production in the pellet-fed group while no gas was present in the cultures made from the dehydrated apple group (Plate I). As the cecum and colon were the only two levels giving satisfactory cultures, these only were reported.

In order to determine the number of cellulose splitting organisms present, cultures on the cellulose membranes were made from the cecum and colon of both groups. It was thought that the group receiving dehydrated apple might show an increase in cellulose splitting organisms due to the presence of hemicellulose and pectin. Serial dilutions were made and incubated under aerobic and anaerobic conditions. It was found that the dietary supplement made no difference in the number of cellulose splitters. The anaerobic plates, however, both groups showed many more colonies than the aerobic. Table III shows the result of the cellulose cultures given in the number of organisms per gram of fecal contents. Since the feeding of dehydrated apple as a source of cellulose did not cause an

a vitamin A free diet plus cod liver oil. In addition, the food of one group was supplemented with dehydrated apple (25 per cent). One animal from each group was sacrificed at ten-day intervals and cultures of the intestinal contents were placed on the modified Aschner media. The last animals sacrificed had been on the diet 42 days. All cultures were made in duplicate and incubated under aerobic and anaerobic conditions. No difference in the number of cellulose-splitting organisms could be detected in the two groups. It is hardly to be expected that the addition of apple to the diet of an herbivorous animal would result in any material change in the number of cellulose-splitting organisms. Alteration in the fecal flora of the rat, however, is to be expected. That it did not occur may be due to a failure to extend the feeding over a long enough period of time.

DISCUSSION

Many years ago, Metchnikov advocated the use of buttermilk. He claimed that the establishment of an aciduric flora in the intestine was of value in that it tended to supplant putrefactive organisms which are capable of producing toxic and irritating materials.

More recently the apple has been advocated as a valuable adjunct to the diet. Clinically, such additions were found to be beneficial although reasons for this were not definitely known. The data submitted in this report show that this food substance is capable of bringing about many if not all of the same changes in the reaction of the intestine and in the intestinal flora as were claimed by Metchnikov for buttermilk. Evidence is increasing to the effect that certain food substances such as cellulose, hemicellulose and perhaps pectin to some extent, can be broken down in the intestine with the liberation of certain organic acids which may have a specific bactericidal or bacteriostatic value. The most important of these acids are claimed to be acetic, lactic and butyric.

Any dietary regime which results in changing the intestinal reaction to one favorable to the growth of the aciduric type of organisms and detrimental to the development of putrefactive processes should be favor-

TABLE III

ably regarded. Furthermore, more importance from a dietetic standpoint should be given those foods whose residues in the intestine can give rise to substances inhibitory to gas production.

CONCLUSION

The addition of dehydrated apple to the diet of the rabbit gives results similar to those obtained by other workers using fruit. The animals receiving apple had

an increased hydrogen-ion concentration in the intestinal contents. The intestinal flora was changed from one in which *Esch. coli* predominated to one in which the acidophilic type of organism was dominant. Furthermore, the number of gas-producing organisms was considerably reduced. The addition of apple to the diet of both rabbits and rats for a period of 42 days did not alter the cellulose splitting flora of either of these groups.

Health and Nutrition of High Andean Indians

By

CLARENCE WILLIAM LIEB, A.M., M.D.
NEW YORK, NEW YORK

STUDIES of the dietary habits of primitive races in relation to their physique, longevity and health status have contributed much to our present day knowledge of nutrition. Notable among these are McCarrison's nutritional researches among the Hunzans in Tibet, Stefansson's observations on the dietary of the Eskimo, Escudero's study of the eating habits of the gauchos of Argentine Pampas, and Metchnikoff's deductions from a study of the Bulgarian peasant dietary.

It was my privilege during the summer of 1937 to study at first hand the eating and hygienic habits of the Indians of the Lake Titicaca basin in Peru and Bolivia. Inasmuch as very little seems to have been written about these people from a medical standpoint it seems justifiable to record some of my observations and deductions concerning their nutrition and the diseases from which they suffer. I am greatly indebted to Dr. Abilardo Ibanez, General Director of Military Sanitation of Bolivia, Dr. Frank S. Beck, of the American Clinic at La Pas and Dr. James V. Price, Chief Surgeon at the Cerro de Pasco Mines for many years, for much of the information contained in this paper.

The Indians, one of the chief ethnical elements of the Bolivian nation, are called AYMARAS. They occupy the Andean plateau extending from southern Peru and take in the shore and islands of Lake Titicaca and extend as far south on this plateau as Auro.

A discussion of the climate of the Lake Titicaca basin is of fundamental importance in a consideration

of the health status of its inhabitants. The lofty plateau, called Calloa, containing the lake basin, has an elevation of a little over 14,000 feet, about the height of our Pike's Peak. Its nearest boundary is about 11° from the equator. The climate is severe, even in summer when there are biting winds, and in the winter when the plateau is swept by violent gales and hailstorms. In the winter the temperature goes a little below freezing, but in the direct sunshine it is almost hot. There is about 20° difference between the day and night temperature. The snow capped mountain ranges, 75 miles in length, may be seen less than 100 miles away from the center of the lake. Lake Titicaca never freezes over, though ice may form in the shallow water. The rainfall is less than 10 inches.

The soil is sandy, but fertile, as evidenced by the luxurious gardens around the watering tanks along the railroad. On the banks of the lake there are terraced garden plots but the variety of the crops is limited to a few hardy plants including the potato (which originated here). No manure or other fertilizer is used and the land is allowed to lie fallow for periods. After so many hundreds of years of cultivation, without fertilizer, the land must have had its mineral content tremendously reduced, with resulting low mineral salt content of its food products. The vitamin content must also be low.

The Aymara Indian is small of stature, being a little taller than the Labrador Eskimo but a trifle shorter than the Japanese, averaging about 5 ft. 4 in. He has a well developed chest, small bony framework,

with muscular arms and calves. The feet are small in spite of his barefoot habits. The head is large with wide, high cheekbones like the American Indian. The neck is thick, the nose large, lips full and eyes small.

The intelligence of the Andean Indians developed greatly under the Inca rule. They became obedient, industrious and thrifty, but these good habits were transformed by the cruelties inflicted upon them by their conquerors. In addition to being exploited and being normally melancholic and handicapped by bad food, bad housing and year-around cold, they have become sulky creatures and the impression one gets is not a favorable one. They laugh, it seems, only when they are drunk. They are dominated at all times by whites and half-castes, public officials, priests and sorcerers. They have many good qualities, being frugal, submissive and docile when kindly treated. The women are never idle, even at rest you see them making yarn with their crudely made distaffs. They make most of the family's clothing.

Their hair is thick, black and straight. Beards are rarely seen. One observes a few hairs on the upper lip, but nothing which one could dignify with the name "moustache". Inquiries brought out the interesting fact that grey hair is a rarity among men and women, no matter how old. The hair rarely falls out and baldness is extremely uncommon in spite of the prevalence of syphilis. Contrary to some medical opinion as to the effect of hat wearing in producing baldness, the Andean Indian wears a hat almost from the day he walks. It is pulled down tightly on his head because of prevailing winds, and shields the scalp from the sun's rays. Both of these effects, circulatory constriction and obstruction of actinic rays should, theoretically interfere with hair growth, but such is not the case.

A study of the teeth brings out certain points of nutritional interest. In general the babies' dentition is delayed about six months longer than the civilized child. They nurse until about the eleventh month. Children after weaning get very little milk as it is quite scarce. There are very few goats in Bolivia and their milk is not used as food. Llama milk likewise is not used. Cows are now becoming more numerous and their milk is gradually being added to the diet. An interesting point with reference to sanitation and cow "psychology" is that the calf sucks at the same time the cow is being milked.

At fourteen, teeth are frequently absent due to dietary deficiencies. This is noted in the Indians living near railroads where civilized food is obtainable. Those living near a sugar plantation have a great deal of dental caries, which seems to confirm the commonly accepted belief that an excess of sugar hastens tooth decay. It is my opinion, however, that the sugar itself is not so much the direct cause of decay as is the replacement of other important vitamin and mineral salt containing food by sugar. The third molars erupt late or not at all. Anomalies of the teeth are rarely seen. At the age of twenty any teeth which have survived the ravages of caries are about level with the gum margins as the result of chewing very hard shelled beans.

The Andean zone of Peru and Bolivia contains a population of about 8,000,000, most of whom are Indians. The Indian population has been stationary for the past two or three hundred years. Large families

are rarely seen, the average being less than four. Over 25 per cent of the marriages are childless.

Infant mortality is appalling. It is not unusual for a woman to have had a dozen pregnancies with but one living child. Dr. Price told me of one woman, who had had twenty children with but one living. Dr. Beck informed me that of 2,500 recorded births 1,600 died before they were one year old, and of these 25 percent died of whooping cough, a disease which seems particularly devastating among these people.

Parental love seems to be of a very indifferent type. As an example, I may mention the case of a gardener who did not appear for work one day. When asked the following morning the reason for his absence he cheerfully replied that his three year old child had died. His employer, after expressing his sympathy, was shocked by the gardener's reply: "Good luck for me, one less mouth to feed."

Abortions are very common. The Indian women often accomplish this by pounding on their abdomens. Midwives function here in a very primitive manner and produce abortions by inserting foreign bodies. Should the mother not succeed in aborting the unwelcome child she may dispose of this child after birth in the following manner. An infusion of the shells of the native peanut is given the infant. This acts as a slow poison. The infant succumbs in two or three days. Dr. Beck tells me that when such a mother resides in the neighborhood of a clinic or a missionary physician she will bring the baby to the clinic doctor after it has been given the poisoned infusion. The doctor examines the baby, notes that it is ill and prescribes for it. The following day the mother reports to the doctor that the baby has died and asks for a death certificate. The doctors are now aware of this method of infanticide and acquaint the civil authorities whenever a case looks suspicious.

The life of these Indians is severe and hard in the extreme, though they are never faced with actual starvation. The diet consists practically of meat, potatoes, corn (mote), very few vegetables and very little butter, sugar, fruit or milk. They eat when they are hungry, hence meal periods are irregular except for those working in mines or other "civilized" jobs. They are small eaters and according to Dr. Ibanez average about 800 calories daily. Gorging is therefore, confined to feast days.

The potato, in the form of chuno, is the mainstay of their diet. The crop is harvested about June first, spread out and covered with straw and allowed to freeze for several days. The potatoes are then intermittently exposed to the sun which causes the water to exude, and to frost. They are turned repeatedly and soon shrivel up. Then they are mashed, leaving a substance similar to coarse starch. This farina-like material is then stored in tightly closed skins. It can be kept indefinitely and throughout the year is the major item in their diet. Oca, a kind of sorrel, quiona, and edible chenopodium, and a specie of millet are used to make soup. Everything is strongly peppered. On account of the poor cooking facilities very little extremely hot food is taken. Chalona, lamb's flesh dried in the sun, and sometimes the flesh of the llama is used. In the lake region, fish, mostly carp, enters quite largely into the diet.

The endurance and speed of these Indians is amazing. The men carry a load of 60 to 80 pounds from 20

to 30 miles without apparent fatigue. When they do not carry a burden they can cover 50 miles a day for several consecutive days.

The houses are made of mud which is baked firmly in the sun. Practically no furniture is used, the bed consisting of a slightly elevated mud platform, over which dirty rags and skins are spread. In all my travels I have never encountered such personal filth. Hygienic conditions are deplorable, entire families being crowded in a gloomy, crowded, filthy hut. Indian servants of the white Bolivians in the Lake Titicaca region are treated almost on a par with dogs. They sleep in some dirty corner of the house and are fed on scraps. The squatting position which is assumed widely is a protective measure serving to keep them warm by covering the lower extremities. Small fires are made of llama dung, bits of dried grass or roots over which food is cooked. The natives do not seem to feel cold at all, although I stood about clad in woolen socks, muffler and heavy suit and overcoat. They walk barefooted in the heaviest frosts or may wear sandals made of skin, but rarely are stockings worn. I saw Indian women standing in the shallow waters of Lake Titicaca, for an hour at a time, when there was ice along the shores.

Bathing is never indulged in as the water is too cold and there are no facilities for heating it. Clothes are only removed when they wear out. The women put on a skirt at an early age and as this one becomes worn another one is put on over it, so that frequently you see a woman of twenty years of age who is wearing a dozen or more skirts. They sleep in their clothes to give themselves added warmth at night. When windward of one of these women a sickening ammoniacal odor gives mute olfactory testimony of their presence. The exposed parts of their bodies, face, feet and hands always appear dirty. Body lice and head lice are very common. Bed bugs are not found in the highlands but are a pest in the lowlands, as every tourist will attest.

These Indians drink very little water and appear to be in a state of chronic dehydration. Constipation, in spite of their meager diet and the use of coca (cocaine) does not appear to be a racial characteristic. This may be explained possibly by their active lives, the absence of chairs, and the habit of squatting while resting. It is a ritual, at the end of each day, to wander from their huts and spend at least fifteen minutes in the squatting position for the purpose of elimination. No log, limb or other support interferes with intra-abdominal pressure.

Since the Chaco War, tuberculosis, particularly of the bones and glands has become very common among them. When they went to the low Chaco country and lived under abnormal dietary and climatic conditions the toll from tuberculosis was tremendous, vastly more dying from it than from lead and steel. Those who survived carried the disease back to the highlands where, on account of unsanitary conditions and nutritional inadequacies, it spread rapidly.

Pneumonia is fairly common and while usually fatal to whites, the mortality among the natives, from the data obtainable, does not appear to exceed civilized statistics. Bronchitis is common. Colds are frequent though sinus infection is not frequently diagnosed. Hay fever, apparently, does not exist. Asthma is a rarity, due possibly to the scant vegetation, rarified air or low streptococcal virulence.

Skin lesions are common. Large ulcers of the shins, forearms and cheeks are frequently seen, due to a form of Leishmaniasis. Treatment consists of intravenous injections of tartar-emet, except when there is involvement of the liver and lungs. A very contagious form of pustular dermatitis, probably impetigo contagiosum, is common and is frequently seen on the face and often covers the entire body. All the other contagious diseases of childhood are found frequently and are similar to those observed in this country. Carbuncles are common, particularly on the neck.

Arthritis of all types is conspicuously absent in the highlands, but, according to my advisors, is quite common in the lowlands. This came as a surprise to me considering their deficient dietary, and cold, damp indoor and outdoor climate in which they live. This might be of interest from the standpoint of that bogey of rheumatology, "metabolic" arthritis. The absence of gonorrhoeal arthritis, atrophic arthritis and streptococcal diseases suggests low pathogenicity of streptococci at high altitudes.

Cancer of the gastro-intestinal tract or skin is rarely seen. Cancer of the uterus is just about as common as among civilized women. Contrary to the prevalent belief about the physical fitness of primitive women, gynecological pathology is about as common, abnormal births as frequent and labor and post-delivery convalescence about as long as that of civilized women.

There is a great deal of typhoid fever among both the Indian and whites. Ulcerative colitis was never seen among the Indians and rarely among the whites. Mucus colitis was occasionally seen. Amoebic dysentery does not exist in the higher altitudes. Typhus fever is very common. Tetanus has not been seen at the American Clinic at La Pas for 10 years. Anti-tetanus treatment is never given.

Dr. Beck told me that it is a safe estimate to conclude that 40 or 50 per cent of the Indian population has syphilis. Tertiary syphilis is never seen among the highland Indians. This fact has, of course, been noted among other primitive people, but it appears that the highland Indian is particularly immune to the tertiary form. This fact offers an interesting field for speculation because his life span favors the tertiary stage. Are genetic, climatic or barometric factors responsible for this changed host-parasite relationship?

High blood pressure is uncommon. Endocarditis and septicaemia are rare. Coronary disease is definitely less common among both the whites and Indians, due undoubtedly to more simple living and less worry and haste.

Those who survive 20 years of age stand about the same chance of living to be 60 as do civilized persons. The men and women at 40 often look 60.

Cataracts are very common. Blindness of venereal origin is prevalent. According to Dr. Beck no basal metabolism studies have been made in Bolivia. Hyperthyroidism occurs only occasionally. Simple goiters are not observed at high altitudes but are common in valleys below 10,000 feet.

Diabetes is rare among clinic cases. Rickets is not observed to the degree or with the frequency that one would expect. Gall bladder diseases are infrequent among hospital cases and no case of cholelithiasis has been found at the American Clinic. Cirrhosis is but rarely seen. Cases of jaundice are extremely rare.

Nephritis is uncommon. No kidney stones have been noted, in spite of habitual dehydration and low vitamin A intake.

Cocaine, (derived from the chewing of coca leaves) and not food is their first necessity of life. They carry a little bag of coca leaves as well as a little pouch containing a mixture of lime and wood ash. It is interesting to note that their ancestors hundreds of years ago empirically discovered that the alkaloid cocaine could be extracted from the leaves in an alkaline medium. The technic is to mix a few crushed coca leaves with a few pinches of wood ash and lime making a quid which they use as we use chewing tobacco. One rarely sees an Indian without a bulging cheek. The leaf itself I found practically tasteless. I chewed the mixture for 15 minutes and felt no immediate feeling of euphoria though I did note a definite loss of appetite at the next meal period. The coca does not produce accumulative effects in the manner in which the Indians use it, though it undoubtedly has contributed greatly to the dullness of intellect which seems to characterize them. Its effect is apparently twofold. It seems to be moderately stimulating, thus making up for the depressing effect of a low blood sugar, which must result from their low caloric diet. Likewise, it unquestionably inhibits gastric secretory and motor function besides dulling hunger sensations. I inquired of the three physicians interviewed about the effect of the coca habit on the gastro-intestinal tracts. According to their observations the habit, even in habitues of long standing, produces no pathological condition. The effect seems to be conditioned by altitude and climate, and appears to play a compensatory role in a biochemical adjustment to high altitude. They rarely reach a toxic stage and it appears that tolerance is not established, as they continue to take the same dose over a period of years. As is well known, cocaine, first stimulates, then produces hallucinations followed by signs of mental and moral laxity. Unlike the taking of opium it can be stopped at once without withdrawal symptoms. While chewing coca leaves Indians can undergo great exertion, and work intensively for long periods of time without apparent fatigue and with very little food. Dr. Ibanez told me that he is convinced that the coca leaf supplies considerable vitamin C. Is it not reasonable to think that the lime and wood ash minerals play an important role in correcting the deficient mineral intake?

Alcoholism ranks with coca leaf chewing as a major vice among these people. It is quite evident, judging from experience with our native Indian and his "fire-water" that the brown race cannot drink with moderation. The Andean Indian does his "two-handed" drinking on holidays. But inasmuch as holidays and work-days seem about evenly divided, he is, for all practical purposes, in a mild state of chronic alcoholism. His favorite drink is white man's alcohol, which he usually dilutes with an equal part of water. He seems to have an extraordinary capacity for oxidizing alcohol, as it is not uncommon to drink several bottles of rum on special feast days. All financial surpluses above bare living wants go for the purchase of alcohol in one form or another. They drink Chicha made from maize which is allowed to germinate. Water is then added followed again by alternate drying and moistening, after which the mash is baked. Water is then added and fermentation takes place. This is called their

"luxury beer". It has twice the alcoholic content of our own beer, and is quite pleasant even to the civilized taste. Another drink which I am frank to say, I did not sample, which is called Chicha-mascada is made as follows. The old folks who are too feeble to work, spend their hours of leisure in chewing maize and expectorating the resulting mixture into a common bowl. This "salivary" concoction is then allowed to ferment, resulting in a drink of high alcoholic content. After mentally analyzing the biochemistry of this beverage, it suddenly dawned upon me that in view of the prolific and protean flora and fauna in the mouths of these Indians an alcoholic extract of these organisms might result in a vaccine incorporated in the beverage. One cannot help but conclude that the Andean Indian's love of drink is due to the neutralizing effect of alcohol upon the secondary depressive effects of chronic cocaine poisoning.

It is exceedingly interesting and instructive to study the medical practices of the early Incas, and that of their descendants of today. The physician in those early days was apparently a man of high moral character and greatly respected. Judging by ceramic evidence and from the numerous trephined skulls exhibited in the Lima Museum, the ancient Peruvian surgeons operated on the skull frequently. It has been estimated that about 2 per cent of the population was trephined. Epilepsy was apparently a major indication and though uncommon today, was quite prevalent at that time as a result of depressive fractures and wounds inflicted by clubs and stone slings. A sharp instrument made of obsidian, a hard black glass, a product of volcanic action, was their favorite implement. The patient before being trephined chewed coca leaves which produced a mild general anaesthesia. During the operation the area was bathed in an infusion of red willow bark which apparently has some antiseptic power. Mashed coca leaves were also applied to the wound to deaden the pain. The wounds were usually dressed with hot oil over which was placed cotton fiber, derived from a plant which was indigenous to Peru. Blood letting was a common practice even though they did not understand the anatomy of the veins. The lancet made of sharp pointed flint was inserted in the vein nearest the point of pain. Cupping was also used by these ingenious peoples. They cut off the end of a cocanut shell and produced a vacuum with it. The Indians today practice the custom of piercing the temporal artery with a sharp piece of glass. This type of bleeding is commonly used.

The Inca pharmacopoeia included the Chillcha herb, used for the relief of pain in the joints; Mamasa leaves, as an astringent, finely powdered tobacco for colds or bronchial conditions; the bark of the Malle tree for healing; a purge made from roots; glandular extract made from the rooster; and of course, cocaine. As diuretic they use an infusion made from corn silk, which seems to be as effective as some of our more refined diuretics. The Aymaras Indians use about one hundred different herbs, which should provide an interesting pharmacological study.

The Collaquayas, Bolivian medicine men who travel up and down the Andes practicing all kinds of strange medical customs, apparently have a certain kind of medical and botanical knowledge, which has come down through the generations. Some of the herbs which they use have been shown to possess therapeutic prop-

erties. These Indians travel all over South America giving treatment with an assortment of seeds, resins, plants, roots and leaves. As their supply gives out they replace them with substitutes. It is quite apparent that autosuggestion plays a definite role in their armamentarium.

Considering the climate and hard struggle for existence and the small number of products of the soil it is rather strange that human beings should continue to live in so inhospitable a land when it is but a few days journey by foot to the East whose hot valleys and abundant vegetation afford vastly easier conditions of living. In spite of the civilized surroundings which have crept into their midst the high Andean Indians present racial characteristics today very similar to those existing before the Conquest. We, therefore, have for our study a great population of primitive people who have lived $2\frac{1}{2}$ miles above sea-level, under unfavorable circumstances and cruel exploitation for over 400 years. Yet in spite of all this they are more advanced in the arts of life than their neighbors who live lives of ease in the tropics.

The following comments by Huntington in his book, "Climate and Health", may condone some of the shortcomings of these Indians.

"If immigrants possessed of an unusually high inheritance, either by reasons of strenuous natural selection or by actual biological mutations, should come to such a region, the relatively stimulating quality of the climate would combine with their innate ability to enable them speedily to dominate the indigenous population, and to develop many new ideas. Yet we should not expect such a civilization to endure so long

or rise so high as those in more favored regions. The people would tend to exhaust themselves for they would never experience any restful changes of seasons, and would be stimulated at all times. The most nervous people would die out partly because they would exert themselves too strenuously, and partly because nervousness is a potent agency in reducing the birthrate. Self-control would also be weakened, thus leading to vice and excesses of various kinds. In various other ways such a climate as that of Peru would be stimulating for a while, but would lead to exhaustion sooner than would one where greater variability prevails."

We must, therefore, be generous in our appraisal of the high Andean Indian. Though they are not likable in character, we must remember that cold, high altitude, meager food, subjugation, exploitation, disease, cocaine and alcohol poisoning have made them surly, cruel, pugnacious, uncooperative and fanatical. It is my belief that kindness, improved environmental conditions, proper medical care and intelligent educational and religious training would entirely change the character of these people and make them into a peaceful, sober, healthy race which would soon lift Bolivia out of its doldrums. When one realizes how much the great mining companies owe to the Indian, without whose special physical aptitudes mines could not have been successfully operated, it seems only logical that the mine owners and their governments should give constructive thought to the welfare of these people. A hospital ship on Lake Titicaca, which has a shore line of nearly 400 miles, would bring them inestimable health benefits.

Editorials

HUNGER, APPETITE AND THIRST

THE physician is often much concerned over the inability or unwillingness of a particular patient or child to eat, and sometimes he turns to the physiologist for some hint or explanation. Unfortunately, the physiologist cannot as yet help much, but, as will be seen from what follows, he has been doing some thinking on the subject.

Hunger is doubtless made up of several components, and some persons experience one type of sensation and others another. Besides sensations referred to the epigastrium, there are feelings of weakness and a desire for food.

Some authorities believe that hunger is produced by contractions of the stomach or the bowel; others that it is due to a group of sensations reaching the brain from many parts of the body; others that it is due to a lowering of food supplies in the blood, and others, that it is due to changes in the brain.

Contractions of the empty digestive tract are not the sole cause of the hunger sensations. Patients have continued to experience hunger after complete or partial gastrectomy. Distention of the stomach with non-nutritious material may relieve for a short time the epigastric discomfort but not the hunger. That

emptiness of the stomach is not essential in producing hunger is shown by the fact that patients with pyloric obstruction and a full stomach will still get hungry. Rabbits also get hungry although their stomach is never empty. Furthermore, hunger does not come simply because the stomach has emptied; it does not come necessarily after hours of fasting. Many persons are not hungry in the morning after the longest fast of the day. Curiously, the taking of black coffee or a sedative, or the smoking of a pipe, may for a time relieve hunger.

People get hungry for certain specific foods. The stout woman on a reduction diet, with her stomach filled with salads and vegetables, may still be ravenously hungry for a pork chop. People compelled for a time to eat fish may remain hungry for beef. Rats on deficient diets are hungry for the foods that they need to supplement the feeding. That mere eating does not satisfy hunger is shown by the fact that a dog with an esophageal fistula when "sham fed" keeps gulping food for long periods of time.

Part of the sensation of hunger is doubtless due to the lowering of the body's stores of food in blood and liver. The patient with exophthalmic goiter and a fast metabolic rate is likely to be abnormally hungry,

but the man whose fast metabolic rate is due to fever is not hungry.

The diabetic is hungry in spite of the fact that his blood is full of sugar, and the obese are very hungry in spite of a normal metabolic rate and large bodily stores of food. Perhaps their trouble is that they inherit a peculiarly sensitive hunger mechanism. The pregnant woman is often hungry, as she should be with her increased need for food.

The very thin, who should be hungry, usually are not. Hunger does not increase steadily during fasting but *commonly lets up on the third day*. That hunger is not due in most part to the need for replenishing the body's stores of food is shown by the fact that in many patients the sensation disappears as soon as a few mouthfuls of food are eaten.

In normal persons the level of the blood sugar does not always influence hunger. The intravenous injection of glucose, however, can stop hunger in dogs and men. The injection of emulsified fat into the blood of dogs does not appease hunger. In man and dogs jejunal feeding regularly relieves hunger in some individuals and not in others. Wherein lies the difference no one knows. After vagotomy such feeding is not so likely to appease hunger, but after section of both the vagus and splanchnic nerves animals continue to desire food. In dogs, distention of a Vella segment, cut away from the rest of the small bowel, will take away all the dog's interest in food.

Hunger can arise from a diseased brain, as in cases of bulimia. Hunger can be removed by an inadequate diet and it can be restored sometimes by giving vitamins or an adequate diet. Sailors will continue to eat and digest even when constantly seasick.

Appetite appears to be different from hunger. It causes people to go on eating after hunger has been appeased. There is a large psychic component. Hungry persons may refuse to eat because of lack of appetite for the food presented. Animals have a sixth sense which shows them what they need to eat to balance the diet and avoid illness.

Thirst has been thought to be due to dryness of the pharyngeal and esophageal membranes, but this is not the essential factor. Thirst can be produced by injecting intravenously hypertonic solutions of salts, and after dehydration of the body it can be relieved by the injection of physiologic saline solution. In diabetes insipidus the primary trouble appears to be an increase in thirst. If an excess of water is not taken there is no polyuria, and if polyuria is prevented, polydipsia remains.

Recent studies have shown that the amount of water drunk by a thirsty animal is exactly what is required for its metabolic needs. Other studies show that the amount of water needed is correlated closely with the surface area of the body.

Walter C. Alvarez, Rochester.

THE STRANGE ABILITY OF ANIMALS TO CHOOSE A BALANCED DIET

ONE of the most remarkable and as yet unexplained faculties of animals is their ability to recognize and pick out not only the foods which they need to supplement a defective diet, but also foods which are doing them harm. Years ago I was much impressed when McCollum told me of the difficulties the early experimenters had before they realized that rats, when

given a mixture of foods, would to their advantage pick out certain substances and reject others. In the early days of dietetic research this explained some of the discrepancies in the results of different workers because some had mixed and pulverized the food while others had not. Later it became customary to supply all food in a mixture ground so fine that it was impossible for the animals to choose or reject any particular set of particles.

A few years ago I was astonished again when Franke, in the South Dakota Experiment Station, told me that his rats would, within a few days, recognize the fact that wheat, containing perhaps 7 parts in 1,000,000 of selenium, was causing their ill health. If then allowed to choose between two samples of wheat, one normal and the other containing the poison, they would reject the latter, and, if supplied only with selenium-containing wheat, would go hungry rather than touch it.

It is curious that a rat should have a faculty which is not possessed to any great extent by adult man. As every allergist knows, there are thousands of men and women in the United States today who go on suffering miseries of many kinds without ever suspecting that these are due to the eating of one or more of the commonly used foods. More curious yet is the fact that infants and children seem often to sense the harmfulness to them of certain foods, such as milk, which they then valiantly refuse to touch. This was once thought to be due to simple stubbornness and natural cussedness, but today every allergist pricks up his ears on hearing of these dislikes because often they point to the fact that, in infancy, the milk did much harm and the child sensed in some unknown way something which was not suspected by his mother or perhaps even by his physician.

That these sensitivenesses can be recognized even in infancy was shown recently by the experience of some friends of mine. When their child was a few months old, he was started on the usual feedings of orange juice. For a few days he took it with great delight, but then he began to bloat and to have abdominal pain. Before his parents and the pediatrician could be sure that the orange juice was responsible for this turn of events, the baby had made his diagnosis and had expressed strongly his determination to swallow no more of the allergen. Actually he was right, and when the feedings of fruit juice were stopped he was comfortable again.

In a recent paper, Richter, Holt and Barelare (Am. Jour. Physiol., 122:734-744, 1938) report their studies of the way in which rats will select their diet when given a chance to do so. Actually the animals were found to be good at picking out a balanced diet with all the necessary vitamins and nutritional substances. Apparently they have a special appetite, not only for salt and sugar, but for protein, carbohydrate, sodium, calcium, phosphorus, potassium, and the vitamins!

It will doubtless be somewhat of a blow to many persons to realize that a rat has in some ways more sense than has homo sapiens!

A NEW TECHNIC FOR THE STUDY OF IMMUNOLOGIC AND ALLERGIC REACTIONS

A NEW and most interesting method of approach to the problems of immunology and allergy has been made by Shaffer and Dingle (Proc. Soc. Exper. Biol.

and Med., 38:528-530, 1938). These men took advantage of the marvelous new methods which have recently been developed by Langmuir and his coworkers for the adsorption of substances onto the surface of suitable plates with the formation of extremely thin monomolecular layers. In these layers the molecules will all be arranged in the same way, with perhaps a long chain toward the plate and a short chain toward the air. The thickness of the film can easily be measured with the help of suitable optical technics, and the several properties of the molecules and the ways in which they combine with other substances can be studied as never before was possible.

Shaffer and Dingle have been making such a layer with a stearate molecule and then studying the ways in which solutions under investigation are adsorbed onto the layer. For instance, a 2 per cent solution of crystalline egg albumin, when applied to the surface of stearate, wetted it readily and there was an increase in thickness of approximately 40 ångströms. Some anti-ovalbumin rabbit serum applied to the albuminized area combined with the antigen and increased the thickness by 100 ångströms. That the reaction was a specific one between antigen and antibody was indicated by the fact that no adherence could be obtained

between antiserum and the stearate surface or between normal rabbit or horse serums or heterologous immune serums and the monolayer of antigen.

Interesting was the discovery that on attempting to deposit a second layer of egg albumin on the upper surface of the anti-ovalbumin antibody already adherent to a base of albumin, the albumin solution removed the antibody, leaving attached to the stearate surface only the original albumin layer. This experiment not only shows an analogy to the effect sometimes observed when an excess of antigen is added to an already existing immune serum-antigen complex, but also may indicate the relative forces existing between antigen and antibody as compared with those which bind albumin to stearate.

Interesting observations were made also on the reactions between certain antipneumococcus serums and pneumococcus carbohydrate from the corresponding type of organism.

There is no telling what advances will come from the use of this most ingenious and remarkable technic, but there should be many. There is nothing so important in science as the discovery of a new technic which opens up a new field for research.

Book Reviews

Clinical Roentgenology of the Digestive Tract. By Maurice Feldman. Baltimore, William Wood, 1014 pp., 1938.

THIS is a monumental work which covers well every phase of the roentgenology of the digestive tract. It is well and interestingly written, and few words are wasted. Plenty of headings help the reader to find promptly the particular bit of information that is wanted. There are 358 illustrations which are well printed on good paper so that they show what the author intended them to show.

Extremely valuable to the student and to the writer are the extensive bibliographies at the end of each chapter which give an entrée to the literature.

The man who wants to know how common certain diseases are or what are the probabilities that a puzzling lesion is this or that will find many fine statistical tables to help him. The author is to be congratulated on the wisdom with which he refused to force his enormous material into the old moulds of the chapter headings of the old books.

To judge of the author's wisdom we looked, of course, to see if he agreed with us on certain controversial subjects, and were delighted to find that he does! For instance, in a carefully worded chapter he admits his inability to diagnose chronic appendicitis from the appearance of the appendix in the roentgenogram. With the terrible pressure constantly being brought to bear on the consulting roentgenologist to diagnose chronic appendicitis frequently and positively,

the making of such a statement requires courage and integrity of a high order.

Obviously the making of this book must have been a labor of love. No one but an idealist could have forced himself through the several years of grueling work in all spare hours of the day that are required for the completion of such a big and carefully documented volume. All roentgenologists will want to have a copy within reach, and all of us who are interested in gastro-enterology have been placed in Doctor Feldman's debt.

Food and Physical Fitness. By E. W. H. Cruickshank. Published by Wm. Wood & Co., Baltimore, 148 pages, 1938.

THIS is a practical little volume on the subject of foods, vitamins, mineral salts, nutrition, etc. It is small enough so that a busy practitioner can get quickly the available information and for that purpose quite adequate. There is so much information in this little volume, packed in so to speak and condensed that it should be on the bookshelf of every physician. For the busy man it is impossible to read everything coming out in this rapidly growing field and this book is meant to give such information with the minimum amount of time involved and for that reason should be read, studied and kept as a reference. The price of it being low, two dollars, makes it easily accessible to everyone.

Henry J. John, Cleveland.

RAILWAY SURGEONS TO MEET IN CHICAGO

Never before in the history of the Railway Surgeons have problems been so grave economically, or technique and treatment procedures of such import as they exist this year. The 23rd annual meeting of the American Association of Railway Surgeons will be held at the Palmer House, Chicago, September 19th to 23rd, 1938. This association includes members in practically every railroad company in the United States, as well as the separate group organizations, embracing railroad surgeons of the New York Central System; Southern Railway; Atlantic & West Point R. R.; Western Ry. of Alabama; Illinois Central System; Chicago, Milwaukee, St. Paul & Pacific R. R.; Rock Island Lines; Chicago, Burlington & Quincy R. R.; Chicago and Northwestern R. R.; the Georgia Railway and other road associations. An extremely interesting and highly profitable program has been arranged and all physicians and surgeons are invited to attend the sessions of this meeting as guests of the organization. There will be no registration fee to M.D. non-member guests. In addition to the scientific exhibits, a technical show will be held, including the presentation of new equipment, advanced types of therapy, new pharmaceutical and biological products and the latest techniques in many branches of the profession. A cordial invitation for you to attend is extended by Dr. Harvey Bartle, President of the Association. Complete program and information regarding the meeting and the exhibits may be secured by addressing Mr. A. G. Park, Convention Manager, the American Association of Railway Surgeons, Palmer House, Chicago, Illinois.

CONNOR, CHARLES L.

Fatty Infiltration of the Liver and the Development of Cirrhosis in Diabetes and Chronic Alcoholism. Am. J. Pathol., XIV, 3:82, 347, May, 1938.

"Direct evidence that alcohol can cause cirrhosis of the liver has been demanded before it is accepted as the primary etiological agent in so-called alcoholic cirrhosis, though everyone knows that the association of the two for centuries has been that of a cause and effect relationship." With this opening statement the author introduces the underlying theme of his study.

The mechanism by which cirrhosis of the liver develops has not been understood. The author reviews

briefly the history of the subject from the observations of Rokitsky (1849), on the presence of fatty livers in heavy drinkers of spirits to the present day knowledge of the association of fatty infiltration and cirrhosis of the liver in diabetes and chronic alcoholism and the experimental production of true portal cirrhosis in depancreatized dogs (Chaikoff, Connor and Biskind. *Am. J. Path.*, XIV, 1:80-101, Jan., 1938).

From his own study of autopsy material and clinical and experimental data and that of other workers the author comes to the following conclusions. Long continued fatty infiltration of the liver is a mechanical factor of great importance in the development of a fibrous tissue retaining wall around distended lobules. Collapse of liver sinusoids and pressure on the peripheral cells of the lobules leads to

The most convenient and
pleasant method of
administering
Gastric Hydrochloric Acid
GLUTAN H-C-L

Indications. The literature shows GLUTAN H-C-L (Glutamic Acid Hydrochloride) to be a superior source of free hydrochloric acid in the treatment of gastric achlorhydria, hypochlorhydria, nervous anorexia, and in secondary anemias requiring a high protein diet, or whenever it is necessary to supplement or replace gastric hydrochloric acid.

Advantages. GLUTAN H-C-L is replacing the old methods of administering hydrochloric acid because—

No unpleasant taste.

No sipping through a glass tube.

No irritation of the esophagus or decalcification of the teeth.

Put up in capsules which may be carried in purse, handbag or pocket—patients appreciate this convenience factor.

Contains glutamic acid, a centuries old condiment—acting with hydrochloric acid the two produce a sense of well being after eating that is novel to patients who have long suffered from anorexia due to hypochlorhydria.

Supplied. GLUTAN H-C-L is put up in capsules, each of which is approximately equivalent to 10 minims of diluted hydrochloric acid U.S.P.

Bottles of 100, 500, and 1000 capsules.

Fill in and mail the attached coupon for a clinical sample and descriptive literature.

a reduction in circulation and a consequent anoxemia. Slow atrophy of the cells is the usual result. The liver that develops extensive cirrhosis has withstood the more acute degenerative changes over a comparatively long period of time.

Connective tissue proliferation begins anywhere in the periphery of the lobules from the cells forming the walls of sinusoids. Frequently it is more prominent around the portal areas but not necessarily so.

From the swollen cells of the sinusoids a delicate reticulum forms around the degenerating liver cells. Fibroblastic proliferation follows these lines and joins with prolongations from the periportal connective tissue. These strands of growing fibrils often define more or less clearly the limits of the lobules, but they also cut across them and form an irregular lobulated pattern.

The disappearance of fat from the liver in advanced cirrhosis may be

due to a combination of factors. The exhaustion of the fat reserves of the body due to gradual starvation is one. When the cirrhosis brings about a chronic passive congestion of the gastro-intestinal tract the amount of alcohol ingested is often reduced and a better diet resumed. Increased intake of carbohydrates, especially of glucose, causes fat to disappear rapidly from the liver. Frequently, as seen at autopsy, all signs of fatty infiltration have disappeared and the quiescent, fibrotic, nodular liver of alcoholic cirrhosis is found.

Fatty infiltration of the liver occurs in those conditions where, because of lack of intake or absorption of food, fat is mobilized from the existing fat depots; and where, because of disturbed metabolism of fat due to anoxemia or tissue anoxia, the accumulated fat in the liver cannot be broken down for use. In the first place it results from external starvation; in the second from an internal or tissue starvation. In both instances normal carbohydrate-fat metabolism does not take place. These states occur frequently in wasting diseases, as diabetes, or in chronic intoxications which inhibit proper tissue oxidation, as in chronic alcoholism. In the latter state actual starvation and a vitamin B deficiency are also usually present. It must be believed that a liver which contains demonstrable neutral fat is in most cases pathological. Its presence may be great enough to disturb seriously both the metabolic and the mechanical functions of the organ. The development of perilobular fibrosis seems to be the result of a combination of mechanical pressure, local tissue anoxia and general anoxemia, which cause atrophy and degeneration of the liver cells.

The alcoholic liver occurs in two forms, one of which is the precursor of the other. The first is the large tense liver, swollen with fat. The excretion of bile and the transmission of portal blood may be so interfered with by increased intrahepatic pressure that clinical jaundice and ascites are present. Such patients frequently die in coma and show at autopsy a large fat liver as the only prominent finding. The lobules are distended with fat and the peripheral cells show hyaline degeneration and atrophy with an early proliferation of fibroblasts. In the second form the proliferation of connective tissue has advanced to the point of showing the typical picture of portal cirrhosis as seen in chronic alcoholism. The gradation of the one into the other is so manifest that the author believes the true mechanism of the production of alcoholic cirrhosis seems to have been definitely demonstrated. The absence of fat in such livers at the end is explained by the exhaus-

Zymenol

Yeast Enzymes in Oil Emulsion

contains the complete natural

VITAMIN B COMPLEX

Clinical work¹ on gastro-intestinal malfunction confirms; the entire Vitamin B Complex gives much more rapid, much more beneficial response than even a very high dosage of the individual factor given in an acute deficiency of that factor.

Zymenol provides the complete natural Vitamin B Complex in high potency PLUS all the enzymes², known and unknown factors of Brewers Yeast and makes them available in a highly palatable, thoroughly stable, well tolerated emulsion of 60% pure mineral oil.

Zymenol restores normal evacuation from natural impulse without roughage, drugs or agents preferably avoided.

Sugar-Free, ideal for diabetics.
No leakage. Less expensive

STREET, A.

"Disease of Gall Bladder and Bile Ducts—Symptomatology and Results of Surgical Treatment." *Southern Surgeon*, 7:299-305, Aug., 1938.

Poor results following biliary surgery for chronic complaints is often attributed to preoperative disease with damage to the liver, pancreas and bile ducts. Incomplete surgery and recurrence of the original disease are also factors. However, a definite number of failures are attributable to the fact that the preoperative symptoms were either caused by disease unrelated to the biliary tract or by non-surgical liver disease. The present study of 197 operated cases was an attempt to appraise the value of symptomatology as an aid to correct diagnosis and prognosis.

Chronic gall bladder disease must be differentiated from (1) nutritional deficiency disease, characterized by malnutrition, weight loss, sore mouth, burning esophagus, smooth tongue, low free hydrochloric acid, and anemia; (2) psychoneurosis with its aerophagia, belching, indigestion, mucous colitis, and insomnia, and (3) less commonly, migraine, arthritis of spine, digestive disturbance of pulmonary tuberculosis, and syphilis of the central nervous system.

Acute gall bladder disease may be confused with acute appendicitis, acute pelvic peritonitis, pneumonia with abdominal pain, coronary thrombosis, gastric crisis of tabes, lead colic, etc.

Significant findings in this review are the preponderance of females, the increased prevalence in the fourth, fifth, and sixth decades, the high incidence of previous typhoid infection, definite weight loss (greater in common duct obstruction) and abdominal pain or colic. This latter appears to be the most dependable of subjective symptoms. The attacks of pain are usually irregular with comfort between seizures. The pain is most often in the epigastrium and appears at greatly varying times after eating. Radiation to the back is more common in common duct disease.

Of the postoperative cases of this series the group obtaining the highest percentage of complete relief were the common duct cases. It is suggested that better results will follow low gall bladder surgery if the symptoms are more carefully evaluated, emphasizing particularly the importance of pain rather than vague per-

sistent digestive symptoms. The fact that patients with more advanced disease may obtain better results, aside from surgical mortality, than those with apparently slight disorders can probably be explained by the greater accuracy of diagnosis and the more certainty of the type of therapy indicated in the severe cases.

J. Duffey Hancock, Louisville.

GRIMES, ALLEN E. AND MASSIE, FRANCIS M.

Regional Ileitis: (With Reproduction of a Case in 1806). Southern Surgeon, 7:251-262, June, 1938.

Regional ileitis represents an acute, subacute, or chronic necrotizing and cicatrizing inflammatory condition, not necessarily limited to the ileal segment of the bowel. It usually occurs in the third decade and affects males twice as often as females. The definite etiology is unknown but the disease in man is probably due to a chronic low grade bacterial infection.

The course of the illness may be acute and fulminating or chronic of several months duration when first observed. The fulminating type resembles other acute intra-abdominal inflammatory conditions, especially

VI-PENTA PERLES

An adequate intake of essential vitamins is necessary for the maintenance of robust health and the full realization of the joy of living. In cases in which a superior pan vitamin preparation is indicated we suggest Vi-Penta Perles. The perles are tiny—actually smallest in size, and yet highest in potency. Note particularly that Vi-Penta Perles are unusually rich in Vitamins A, B, and C. They contain 1½ times the amount of A, twice the amount of B₁, and 2½ times the amount of C, as compared with similar capsules put up by reputable manufacturers. Packages—boxes of 25 and 100, for hospitals, bottles of 1000.

HOFFMANN-LA ROCHE, Inc., Nutley, N.J.

appendicitis, from which it may be impossible to make a differential diagnosis. This acute phase may be followed by diarrhea and other symptoms suggesting chronic ulcerative colitis. If healing does not occur chronicity leads to fibrosis deformity and obstruction at which time the clinical symptoms will be diffuse abdominal cramps, nausea, vomiting, distention, and borborygmus. A mass can generally be palpated because of the tendency for the bowel to become adherent to the anterior abdominal wall and adjacent vis-

cera, more frequently the right colon, but also the sigmoid. This adherence to surrounding structures probably accounts for the fistulae which sometime occur. X-ray examination may be of great aid in the chronic cases if the characteristic "string sign" is present. This is evidenced by a thin slightly irregular linear shadow suggesting a cotton string in appearance and extending from the area of the defect to the ileocecal valve—this shadow remaining constant for hours or even days.

Since spontaneous resolution has

occurred without operation or following simple exploration, medical management for all cases has been advocated by some. However, most advocate one of the following surgical procedures, ileocolostomy alone, ileocolostomy with subsequent resection, or one-stage ileocolostomy combined with resection. Ileocolostomy in poor risks with secondary resection if required is probably the best plan of procedure. Recurrence may follow even a radical resection. The general mortality of the disease has been estimated at 14%.

In addition to complete reports of three personal cases there is included an interesting account of "A Singular Case of Stricture and Thickening of the Ileum" reported before the Royal College of Physicians in London, July 4, 1806, by Drs. Charles Combe and William Saunders.

STONE, CHARLES T. AND SHECKLES, LOYD W.

"Intestinal Tuberculosis: A Pathological and Clinical Survey." *Southern Med. Jour.*, 31:715-720, July, 1938.

Although tuberculosis of the intestine is the most frequent and one of the most serious complications of pulmonary tuberculosis it has not received the attention its importance should demand. This apathy is probably due to the difficulty of diagnosis, the feeling that it is a rather terminal lesion and the belief that it is not amenable to treatment. In a review of 2,220 consecutive autopsies, 284 or 12.9% were found to have tuberculosis in some form, 273, or 12.3%, had pulmonary tuberculosis and 60, or 21% of the total (284) had intestinal tuberculosis, or 22% of the pulmonary cases.

A study of these sixty cases serves as the basis for the observations that follow. The disease was most common in the third to sixth decades inclusive, it was more than twice as frequent in negroes and males predominated. Fifty-eight of the sixty cases showed pulmonary tuberculosis and cavitation was present in fifty-two of these fifty-eight cases. None of the cases showed the disease primary in the digestive tract. The site of preference of the intestinal lesion was the ileocecal region with a greater preponderance for the ileal side. The histories of the patients showed that the chief complaints as stated by the patients were referred to the digestive tract in eighteen cases (twelve of these having pulmonary symptoms as well). In thirty of the cases the chief complaint was entirely referable to the pulmonary system. The duration of the intestinal symptoms, except in three or four cases, was quite short. The most common gastro-intestinal symptoms were an-

Bromo-Seltzer

Its Place in GASTRO-ENTEROLOGY

There is a world of difference between the gentle systemic action of the sodium citrate in BROMO-SELTZER and the harsh *local* antacids such as the bicarbonates. While the latter often damages the normal hydrochloric acid of the stomach, sodium citrate actually aids digestive processes. This has been established by its use in infant feeding, with milk coagulation prevented and a fine flocculation produced.

Gastric Sedative and Analgesic—The sedative and analgesic value of BROMO-SELTZER are widely recognized by the profession. In gastro-enterology, it exerts a gentle sedative action upon the stomach and offsets nausea. Nervousness is minimized.

BROMO-SELTZER is dependable without harmful after-effects or mental depression. Its bubbling effervescence makes it decidedly palatable.

Try BROMO-SELTZER in your practice. Generous samples and literature upon request.

EMERSON DRUG COMPANY

MARYLAND

orexia (often present in uncomplicated pulmonary tuberculosis), abdominal pain, vomiting, and diarrhea. Abdominal tenderness and gaseous distention were the most common physical signs. Gastro-intestinal X-ray study was made in only two of the cases and in neither was the diagnosis made by this means. A clinical diagnosis of intestinal tuberculosis was suggested in only eleven of the sixty proved cases.

Since ultraviolet irradiation alone or combined with X-ray therapy and used concurrently with the general

treatment of tuberculosis ameliorates distressing symptoms and in a fair number of cases is productive of healing additional methods of study must be developed for the earlier diagnosis of the disease. Probably gastro-intestinal X-ray examinations as thorough as those made of the chest may prove to be of great aid in recognizing this complication which which may so impair the digestion and augment the toxemia present as to precipitate a crisis in the patient with a primary pulmonary lesion.

WHITE, RICHARD JOSEPH.

"The Persimmon Phytobezoar—A report of three cases." *Southern Med. Jour.*, 31:750-755, July, 1938.

Human bezoars include the trichobezoar or hair ball, which is by far the most common, the trichophytobezoar, which is primarily hair mixed with fibers of vegetable matter, shellac concretions usually found in painters or shellac workers, and the phytobezoar or food ball by far the most frequent of which is the one caused by persimmons. Bismuth subcarbonate, massive doses of salol, tobacco, etc., have been reported as causing bezoar formation.

Persimmon bezoars are compact putty-lime masses varying greatly in size being frequently multiple. They are fairly soft, can be broken up or molded rather easily and may pass out into the small intestine which may become obstructed. Those fairly fresh have a greenish yellow color. Although it is uncertain why the ingestion of persimmons, usually harmless, should result sometimes in the formation of a bezoar, it is significant that most patients give a history of being unusually hungry and eating ravenously and in great haste of persimmons alone.

The effect of the persimmon ball on the stomach is dilatation of the stomach with redness, congestion, edema and in some instances hemorrhage and ulceration. The acute symptoms are those of a severe gastro-enteritis with vomiting, cramps, purging and fever. These may be followed by a sense of weight in the abdomen, severe nausea, and occasional mild vomiting of water or mucoid substance. Ingestion of food may aggravate or relieve the pain. All the symptoms may vary greatly in intensity. Movable filling defects are the outstanding observation on X-ray examination. Many mistakes in the differential diagnosis of these tumors have been made.

Brilliant results follow surgical removal by gastrostomy or enterostomy. The incision in the stomach should be large enough to admit the examining hand in order that multiple bezoars may not be overlooked. No treatment of the secondary ulcer is indicated as it will heal after the removal of the persimmon ball.

Three interesting cases are reported.

J. Duffey Hancock, Louisville.

ELKHART, INDIANA

For the Aristocracy of Thought*

Your highly valued Journal is made to order for the aristocracy of thought of the Medical Profession of America . . . it has become a habit with me, and I would not care to miss a single issue.

The AMERICAN JOURNAL OF DIGESTIVE DISEASES

Was NOT established as a *vade mecum*, a news magazine, a humorous monthly nor a fictional alleviation for the jaded nerves of busy doctors . . . Most readers by this time have divined this point of policy, and have come to know that, month by month, this periodical gives a cross section of current and modern gastro-

enterological thought. It sees most of the manuscripts in this specialty: it prints all of them that are suitable . . . BETTER articles will be printed only when BETTER articles are written. The reader may confidently believe that at present the best work in gastro-enterology finds its way into these pages . . . Another way of saying that the management of this JOURNAL is seeking to perfect a really worth-while Archive in a most important field.

It is the firm intention of the Editorial Council that the pages of this Journal shall be kept FULL of important matter, and entirely EMPTY of all matter that is irrelevant . . .

Readers feel today that an important contribution to American Medicine is being, and will be, made through the agency of the American Journal of Digestive Diseases . . .

I am an admirer and reader of your excellent magazine.

You cannot improve on the editorial content—it is and should be, an outlet for scientific thought.

Material and format are excellent. I enjoy it very much because the articles are scientific.

It is certainly a well edited Journal and anyone who subscribes to it certainly gets his money's worth.

Quality brevity, educational value, scientific dignity, good typography and singleness of purpose are making friends in increasingly large numbers.

*These are excerpts from voluntary letters received from readers and the names of the writers are on file at the Office and may be had upon application.

No Other Special Medical Journal Ever Made the Subscription Showing in 4 Years That Has Been Accorded to the American Journal of Digestive Diseases

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY?

The reasons are obvious—

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.

- This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases.

Spend \$6.00 per year or \$10.000 for two years NOW.

Join the increasing Group of doctors, whose enthusiasm has made and is making history in American Medical Journalism.

Useful... IN MANY INVALID AND CONVALESCENT DIETS

RIPE BANANAS are a natural, soft, bland food . . . with a delicate flavor . . . popular with most persons . . . nourishing . . . easily digested . . . mildly laxative . . . non-irritating . . . do not readily ferment in the intestines . . . create intestinal conditions unfavorable to the growth of putrefactive bacteria . . . yield alkaline mineral residues in the body.

Because of these attributes, together with their soft fibre, pectins, high content of sugars, satiety value, low content of protein and fat, their vitamins (good source of A-B-C-G) and essential minerals, ripe bananas are prescribed by an increasing number of physicians in many invalid diets, including: ulcerative colitis; peptic ulcer; cardiac; diabetes; liver disorders; nephritis; tuberculosis; as well as in various post-operative and convalescent diets.

In the field of corrective diets, physicians are finding that ripe bananas help combat both diarrhea and spastic constipation; also that in combination with milk they constitute a basis for planning a variety of effective, safe reducing diets for persons who are overweight.

LITERATURE ON REQUEST . . . ADDRESS

UNITED FRUIT COMPANY *Educational Dept., Boston, Massachusetts*

states that the condition was characterized by abdominal cramps and diarrhea in conjunction with severe autonomic disturbance.

Weiss has divided these reflex responses into vagal, depressor and cerebral. The vagal and depressor types are associated with decreased cerebral flow and cerebral anoxemia. The vagal effect is characterized by cardiac slowing or asystole and can be modified with atropine depression of the vagus or with ephedrine and epinephrine stimulation of the ventricle. The depressor effect is char-

acterized by reflex vasodilatation by way of the aortic depressor nerves and is modified by ephedrine and epinephrine but not by atropine. The cerebral type is not associated with cerebral anoxemia and is probably due to a reaction in the vegetative centers of the hypothalamus.

Vagal-depressor and cerebral-depressor syndromes occur and are characterized by dizziness, weakness, hyperpnea, facial pallor, bradycardia, numbness and tingling of the extremities, convulsions, drowsiness, cataplexy, epigastric distress, nausea,

lacrimation, cough, amnesia and palpitation.

The author presents the case of a man who since 1928 had been having attacks of sudden tightness and fullness in the head, confusion, sweating of the hands followed by loss of consciousness. In September, 1936 he developed abdominal cramps, followed by an apparently normal bowel movement. On leaving the bathroom he noticed some cerebral symptoms similar to his other attacks. He again developed abdominal pain and returned to the bathroom where he fell unconscious. Physical examination and laboratory examination were negative. Stimulation of the carotid sinus resulted in symptoms similar to those described in his attacks. He was put upon pheobarbital and atropine and was given atropine, Gr. 1/150, for the acute attacks. In spite of this he had several severe attacks. The right carotid sinus was denervated surgically and subsequently the patient has been free from attacks.

Francis D. Murphy, Milwaukee.

Why Protection of Vitamin C Is An Indication of High Quality In Canned Strained Foods

Aside from the Vitamin C present in orange or tomato juices, strained foods are not expected to supply any appreciable proportion of the requirements of the infant for vitamin C. (1) Yet the quantity of vitamin C in commercially canned strained foods is of interest in the feeding of infants. It also is of importance as an index of the care used to prevent oxidation with resulting destruction of general vitamin content in the preparation of strained foods.

It is known that oxidation takes place when raw products are transported or stored at ordinary temperatures for even as short a time as a few hours. Gerber's vegetables are grown in fields that begin at the kitchen door, and are rushed from fields into cans. Oxidation destroys some vitamin C when cooking is done in an open kettle. Therefore, Gerber's foods are cooked and strained with air excluded under controlled temperatures by processes designed to prevent oxidation during canning. Because some vitamin C will be lost when cooking water is discarded, Gerber uses no water, only steam. (2) (3)

The probable approximate requirement of the infant is 300 international units of vitamin C a day. Gerber's Strained Spinach supplies 150 units in a two-ounce feeding. Two ounces of Gerber's Strained Peas yield nearly 100 units, both because of control of oxidation and because of the use of peas of very small size, which are much richer in vitamins than larger peas. Liver soup has about 25 units, and green beans 35 units. (4)

Free on request: Analyses of mineral and vitamin content of Gerber Strained Foods. Also recent reprints. Gerber Products Co., Dept. 339, Fremont, Michigan. (In Canada, Gerber's are grown and packed by Fine Foods of Canada, Ltd., Tecumseh, Ont.)

Beuzedrine Sulfate: Its Limitations in the Treatment of the Spastic Colon and a Pharmacological Study of Its Effects on the Gastro-Intestinal Tract. J. A. M. A., 110:1394, June 11, 1938.

Benzedrine sulphate has of late been used for a great many conditions. Myerson and Ritno found it to be of value in relaxing the spasm of the gastro-intestinal tract and the pyloric sphincter. They found it useful in spastic colitis and pylorospasm. The authors studied its action in this condition and its pharmacologic action on the gastro-intestinal tract.

In a series of eighteen patients of whom all but two had been receiving and not responding to the usual orthodox treatment, benzedrine sulphate in doses of 5 to 10 mg. was used before breakfast and lunch and in three cases before supper. The results were as follows: three were improved, one was improved but recurrence followed, eleven were unimproved, and three became worse. The drug was found also too unreliable in the uniformity of its results as evidenced by roentgenographic examinations in five patients.

Further investigation showed that on two normal subjects and in the dog it produced pylorospasm, enterospasm and prolonged the emptying time of the stomach.

The authors believe that this drug should not be used in spastic disorders of the gastro-intestinal tract.

Francis D. Murphy, Milwaukee.

IN INFANTILE DIARRHEA

It's Fermentation

PROPERTIES OF KARO

Uniform composition
Well tolerated
Readily digested
Non-fermentable
Chemically dependable
Bacteriologically safe
Hypo allergenic
Economical

COMPOSITION OF KARO

(Dry Basis)

Dextrin	50%
Maltose	23 2%
Dextrose	16%
Sucrose	6%
Invert sugar	1%
Minerals	0 8%

KARO EQUIVALENTS

1 oz vol	40 grams
	120 cals
1 oz wt	28 grams
	90 cals
1 teaspoon	15 cals
1 tablespoon	60 cals.

Intestinal fermentation may be kept at a low level when Karo is fed. The dextrose and maltose components are quickly absorbed. And the difficultly fermentable dextrin is gradually and completely transformed into simple monosaccharides.

The high intestinal tolerance for Karo makes it a suitable carbohydrate addition to the formula of the infant convalescing from diarrhea. Karo may be safely added to protein milk and acid milk formulas.

Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

FREE to Physicians only:

Convenient Calculator of Infant Feeding Formulas: accurate, instructive, helpful. On receipt of Physician's prescription blank, giving name and address, the Calculator will be forwarded. Write Corn Products Sales Co., Dept. DN-9, 17 Battery Place, New York, N. Y.

Kellogg's ALL-BRAN

SUPPLIES:

● Many foods of fibrous content have been suggested as a source of laxative bulk. Such bulk is not available as an eliminating agent, however, unless it reaches the colon undigested.

The effectiveness of Kellogg's All-Bran as a source of bulk lies in the fact that in the average person a large part of its fibrous content does not digest, but provides an ideally soft bulky residual mass in the intestine.

In addition, All-Bran furnishes a significant amount of vitamin B₁, beneficial to the intestinal tonus. Also as a source of iron, All-Bran is especially valuable... because in All-Bran the iron occurs with copper, thus becoming readily available for making hemoglobin.

These contributions by Kellogg's All-Bran to important physiological functions suggest its use as a dietary aid in constipation resulting from lack of bulk. Made by Kellogg in Battle Creek.

BATE, ALEXANDER.

Cancer. Kentucky Med. Jour., July, 1938.

The author attempts to build up an explanation of the etiology of cancer on the basis of a disturbed hydrogen ion concentration of the cells; this disturbance is attributed to faulty endocrine supply. The hypothetical mechanism involves distortion of the assumed intracellular electrical phenomenon within the mutated cell. The thymus gland is held up as the particular endocrine involved. The paper includes considerable recondite argument and involves references to physiology, physics, histology and even psychology.

The contribution presents difficult reading because one is not usually given so broad a field of speculation, and it may be said that it falls into a group of writings which while they perhaps carry little conviction to the reader, are not necessarily without a certain stimulating value.

CONNOTATIONS

By H. J. SIMS, M.D.

Denver, Colorado

In 1886, Lin successfully resected a portion of the liver. Brunn, in 1870, removed a small hepatic tumor.

Endothelioma of the ovary was recognized by Leopold in 1874. He used the term "lymphangioma cystomatosum." The term "endothelioma" was first used by Golgi, in 1869. Pick, in 1894, made a detailed study of this class of tumors and from a morphological standpoint divided them into three classes.

Hotz, of Chicago, successfully used the Thiersch graft for a symblepharon, in 1893.

Leyden, in 1884, suggested that typhoid perforation might be sutured. Mikulicz, in the same year, carried out such a procedure.

It is generally accepted that J. L. Petit, in 1772, was the first clinician to mention subcutaneous rupture of the tendons. Sédillot, in 1786, prepared an essay on this subject. It is believed by some historians that Hippocrates referred to muscle rupture. It is not clear whether Hippocrates referred to subcutaneous rupture or wound rupture.

Gould and Pyle report the case of Gerauld, in which a German woman, 84 years of age, maintained a vaginal pessary more than 50 years.

His, in 1866, first used the term "endothelium" and employed it to describe the cells lining all body cavities not admitting air. Ranvier extended its use to include cells lining lung alveoli.

Morton, of Philadelphia, and Sir Frederic Treves claimed to be the first to remove the appendix, in 1877. It is believed by many that priority should go to Kronlein of Germany, who, in 1884, removed the appendix on the advice of Mikulicz.

Fitz, of Boston, as early as 1886, advocated early removal of the appendix. Symonds of England, and Hall, of New York, successfully diagnosed and removed the appendix in the same year.

Hamilton, in 1884, collected 24 cases of axillary vessels torn in reducing old shoulder dislocation. Fifteen of them died.

Echinococcus of the heart was first recognized by Price, in 1821. Grulee, of Chicago, was the first in America to report echinococcus disease of the heart.

Karl Schroeder of Berlin, in 1880, was probably the first to open the abdomen for rupture of the uterus with a child in the abdominal cavity.

Rokitansky, in 1842, recognized status lymphaticus but confused it with tuberculosis of the lymphatics.

Spine Bifida was recognized by Sherwood, in 1813.

Cavernous angiomas in voluntary muscles, while not common, was recognized by Campbell de Morgan, in 1864. The tumor was congenital and occurred in a girl 10 years of age.

Radical operation for the relief of malignancy of the

RECENT ADVANCES IN THE SCIENCE OF NUTRITION

I. THE ROLE OF RIBOFLAVIN IN HUMAN NUTRITION

● In 1933, a series of articles on the vitamins was published, each article written by an authority in the field of nutrition. These papers served to summarize existing knowledge concerning these essential factors. During 1938 a similar series of articles has been issued. Comparison of related papers in these two series will indicate the most important advances in the science of nutrition which have been made in the course of the past five or six years.

In the first series of articles mentioned above, only two of the better known members of the old vitamin B complex received extended discussion (1). The more recent series, however, is characterized by the inclusion of a number of papers on riboflavin which, since 1932, has assumed a new significance in human nutrition (2). As compared with other factors with which it is often associated in nature, the rise of riboflavin to importance in human nutrition is somewhat anomalous.

For example, the effects upon humans of severe dietary deprivation of vitamin B₁ and the P-P factor are well known, in fact, such effects in themselves afford proof of the indispensable nature of these factors. While riboflavin is apparently concerned in cellular oxidation processes of mammals, the specific effect on humans of riboflavin deficiency is not known. Nevertheless, from the weight of evidence accumulated during the last five years, riboflavin is generally accepted as important in human nutrition. Authoritative opinion concerning riboflavin has been succinctly expressed as follows:

"The fact that we do not know any specific human disease due to shortage of riboflavin is entirely compatible with the view that this substance is important in human nutrition. A detailed discussion of reasons for believing that riboflavin plays a role in the life process of the human as

of other species would probably seem superfluous to a majority of readers at this date, and to a still larger majority in the future. Suffice it to point out that our species has evolved in the direction not of shortening the list of things it needs but of lengthening the list of things it can use to advantage." (2c)

Chemically, riboflavin is described as 6, 7 dimethyl-9 (d-l' ribityl) iso-alloxazine; a yellow-green, heat-stable pigment enjoying wide distribution in the plant and animal kingdoms. Many foods, therefore, of both plant and animal origin supply valuable amounts of this essential factor, specifically, fruits, vegetables, particularly the leafy pigmented types, and animal products such as milk and dairy products, meats, liver, and fish. It may, perhaps, be too early to estimate the daily human requirement for riboflavin. However, one rather liberal recommendation lists 600 units* as required daily by older children and adults; the estimated riboflavin requirement for younger children is somewhat less (2e).

In view of the above facts, attainment of an adequate intake of riboflavin would appear to be best insured by a varied dietary regime which includes the so-called "protective" foods. In the formulation of such diets, commercially canned foods may be particularly valuable. The older "vitamin C" assays—which are now known to measure principally the riboflavin contents of foods—indicate that modern canning procedures are without significant effect upon riboflavin. In addition, many foods valued for their contribution of this factor are canned commercially and hence are conveniently available at all seasons on practically every American market. Therefore commercially canned foods may be freely used in arranging such protective diets and they should materially assist in providing an adequate supply of this newly recognized dietary essential, riboflavin.

**COLLOIDAL
ALUMINUM
HYDROXIDE**
(TRUESDALE)

THE PRODUCT

- A** *Strictly Ethical:* Frankly labelled Colloidal Aluminum Hydroxide (Truesdale) without recourse to proprietary trade name disguise.
- B** *Rigidly Standardized:* Specially processed to maintain a scientifically predetermined hydrogen-ion concentration, an established degree of viscosity, and a controlled chloride content.
- C** *Faster Acting:* In 10 minutes, when titrated with Toepfer's reagent, will adsorb and neutralize 10 times its own volume of N/10 hydrochloric acid—and in 30 minutes substantially more than 12 times its own volume of free acid.

ITS ACTION

- A** Neutralizes free hydrochloric acid in gastric juice by adsorption, relieving hyperacidity and pain, and preventing digestion of ulcer clot.
- B** Helps to control hemorrhage from ulcer by its astringent action.
- C** Provides mechanical barrier against irritation of ulcer through close affinity of protective film for gastric and duodenal mucosa.

Supplied in 12 oz. bottles, or in gallon containers for continuous drip administration.

Write now for samples and complete literature.

160 East 56th Street
New York, N. Y.

stomach was first performed by Pean, in 1879, and by Rydygier, in 1890. Billroth, in 1881, reported a successful operation.

Ponfick, in 1889, found that forty per cent of the liver could be removed without fatal results. In a series of animals, seven-eighths of the liver was resected and forty per cent of the animals survived. He determined if three-fourths of the liver was removed that regeneration replaced four-fifths of its normal weight. Gluck, in 1890, verified these findings.

In 1803, Portal attempted to classify mesenteric cysts. Augagneur, in 1886, was able to collect 96 cases of mesenteric tumors, 18 of which were cystic. Hahn, in 1877, classified mesenteric cysts on the basis of their contents, namely: blood, chylous, serous and echinococcus cysts.

Desprès, in 1880, reported a carcinoma of the rectum in a child six years of age. This case report has been mentioned in many articles and in text-books. The original article states the child was sixteen years of age. No microscopic examination of the tissue was made.

Küster, in 1896, made use of a transverse suprapubic incision for cosmetic effect. Rapin of Geneva, about the same time, unknowingly introduced the same incision for the same reason. Pfannenstiel, in 1900, modified the transverse incision, believing that less chance of hernia was possible. Stimson, in 1902, unaware of Pfannenstiel's publication described the same incision.

McKNIGHT, R. B.

Appendicitis: A Problem for Public Health Agencies as Well as for Practising Physicians. Southern Med. and Surg., 100:281-283, June, 1933.

Laxatives and delay account for nine out of ten deaths from appendicitis. A survey in Philadelphia covering some 15,000 cases showed that of the patients admitted to the hospital within 24 hours of the onset of the attack, 1 in 49 died, within 48 hours 1 in 21 died, within 72 hours 1 in 16, and after 72 hours 1 in 11 died. As regards laxatives, where no laxative was given 1 in 71 died, where one laxative was given 1 in 18, and where more than one was given 1 in 8 died.

It is a generally accepted fact that purgation and procrastination account for 90 per cent, or over, of the deaths from appendicitis. It is estimated that in the United States, appendicitis causes an annual loss of over \$100,000,000, approximately 90 per cent of which could be, and should be, saved.

The author urges closer cooperation between medical societies and boards of health in an effort to better acquaint the general public with the dangers of self-medication or delay in seeking proper medical advice in cases of abdominal pain or distress. Reference is made to the good results achieved in Philadelphia as the result of an educational campaign.

Hanes M. Fowler, Fort Wayne.

METZ, M. HILL AND LACKEY, ROBERT W.

Peptic Ulcer Treated by Posterior Pituitary Extract. Texas State Jour. of Med., 34:214-220, July, 1938.

The authors report satisfactory clinical results in 40 of 42 patients with peptic ulcer treated with posterior pituitary preparations. The duration of treatment averaged twenty-eight days, but subjective improvement was present after one to eight days. The use of posterior pituitary preparation in treatment was suggested by the observation of polyuria associated with the ulcer syndrome.

Intra-nasal insufflation of the posterior pituitary powder proved to be the most satisfactory mode of administration.

A photograph and description of the nasal insufflator used is included.

Hanes M. Fowler, Fort Wayne.

ADEQUATE IRON

for Hypochromic Anemia

Excellent hemoglobin response results in most cases from the daily dose of three Hematinic Plastules Plain. This provides 15 grains of ferrous iron.

Small dosage, easy assimilation and toleration favor the use of Hematinic Plastules for hypochromic anemia, because they produce maximal results, at low cost, without discomfort or inconvenience to the patient.

Hematinic Plastules provide ferrous iron and the vitamin B complex of concentrated yeast, in soluble gelatin capsules. They are issued in two types — in bottles of fifty — Hematinic Plastules Plain and Hematinic Plastules with Liver Concentrate.

THE BOVINE COMPANY • CHICAGO, ILL.

Research, Constant Research

continues to improve the quality of Mead's Brewers Yeast in the following respects, without increased cost to the patient:

1. Vitamin B potency raised to not less than 25 International units per gram. Also contains 42 Sherman vitamin G units per gram.
2. Bottles now packed in light-proof cartons, for better protection.
3. Improved bacteriologic control in harvesting and packing.
4. And NOW, since August 1, 1936, all bottles are packed in vacuum. This practically eliminates oxidation. Mead's Yeast stays fresh longer, as you can tell by its improved odor and flavor!

Mead's Brewers Yeast Tablets in bottles of 250 and 1,000.

Mead's Brewers Yeast Powder in 6 oz. bottles.

KONSYL

*the Mucilaginous-Forming
Part of the Plantago Ovata*

RESTORES NORMAL BOWEL ACTIVITY

1. KONSYL does not irritate even the most sensitive gastrointestinal lining.
2. It supplies bulk and therefore assists in controlling intestinal spasm.
3. Its jelly-like consistency forms an effective lubricant for the bowel, and in this way facilitates passage of the feces.
4. Easy to swallow. Does not interfere with the digestive processes, nor does it become digested.
5. Retains its viscous properties in the intestines and forms a stool of semi-solid consistency.
6. Also because of its viscous and non-liquifying properties, Konyl, even when taken in large doses, does not cause leakage from the anus.

Write for clinical test sample and literature.

Also manufacturers of L.A. FORMULA, containing Lactose, Dextrin and Plantago Ovata Concentrate. A.J.-9-34

*Rupture of the Gall Bladder
Without Associated Cholecystitis.*
J. A. M. A., 110:1826, May 28,
1938.

Spontaneous rupture of the gall bladder complicating cholecystitis and cholelithiasis is rare. Rupture without inflammation or stones has not been reported.

The authors present the case of a man whose first complaint was the failing of vision and nocturia. Physical examination revealed a definite severe hypertension with retinal arteriosclerosis, and the electrocardiogram showed coronary disease. Laboratory examination revealed the presence of albumin, red and white cells and granular casts in the urine, but otherwise there were no abnormalities. He was put upon the usual hypertensive cardiac routine and responded for a short time. This was followed by a period of severe cardiac decompensation which was first treated in the hospital and later at home. One morning after being at home he was seized with an excruciating pain in the right upper quadrant associated with a coffee ground vomitus. He was readmitted to the hospital in shock. The blood pressure at this time was 268/100, the temperature 97.2° F. and the respirations 24. A very tender mass was palpable in the right upper quadrant, but there was no rigidity. The blood count was as follows: white cells 6,200, of which 8 per cent were stab cells, 74 per cent segmented cells, 18 per cent lymphocytes, and 1 per cent monocytes; red cells 3,560,000; hemoglobin 67 per cent. A tentative diagnosis of mesenteric thrombosis was made and he was given morphine and supportive treatment. He died 48 hours after admission.

Post mortem examination revealed the usual findings due to arteriosclerosis but in addition there was rupture of the gall bladder with fatal hemorrhage.

Frances D. Murphy

ABBOTT, W. O. AND JOHNSTON, C. G.

Intubation Studies of the Human Small Intestine. S. G. O., Vol. 66, No. 4, pp. 691-697, April, 1938.

The authors propose a method of small intestine intubation by means of which the entire small intestine may be emptied of its contents and the force of peristalsis at any point measured.

A No. 14 or No. 16 F. duodenal tube with a No. 3 F. rubber tube tied tightly to it is passed into the stomach of the patient. On the end of the larger tube is fastened a duodenal bucket while on the end of the smaller one is fastened a rubber balloon of 50 cc. capacity. As the ends of the tubes pass into the duodenum the balloon is

inflated and suction is applied to the end of the larger tube. All intestinal contents are immediately removed and as normal peristalsis returns the inflated balloon is passed down the intestinal tract; the duodenal bucket preceding it. The tube will advance at the rate of about one foot per hour. Care should be taken to avoid its curling up in the stomach as that may inhibit its passage along the intestine. A length of between 8 and 10 feet will extend from the patient's teeth to the cecum.

As the balloon advances it will be stopped by an obstruction in the small bowel, which may be demonstrated roentgenologically by the injection of a small amount of dilute barium mixture. The nature of materials aspirated from the intestine may be studied and by attaching a manometer to the smaller tube the force of peristalsis may be measured.

The author feels that such decompression alone will render operation unnecessary in many instances and facilitate it greatly in many other instances.

The entire tube may be pulled out within 15 minutes or less.

Four figures, a summary table, and some case reports accompany the article.

GRAHAM, R. R.

Technical Surgical Procedures for Gastric and Duodenal Ulcer. S. G. O., Vol. 66, No. 2A, pp. 269-287, Feb. 15, 1938.

Surgical procedures have no place in the treatment of simple duodenal ulcer nor in the treatment of gastric ulcer before adequate non-operative therapy has been tried. The complications of duodenal ulcer such as perforation, penetration, hemorrhage and stenosis require surgical treatment. Surgical treatment of benign gastric ulcer will rarely be necessary if a carefully supervised and adequate period of treatment by intubation will be carried out. Such treatment should be continued over a 3 week period, after which the status of the ulcer is determined and further treatment decided upon. If under such treatment the ulcer is healed in 6 weeks, operation is not required. If after another 3 week period the ulcer has recurred, operation is indicated.

If operation is required for gastric ulcer a subtotal gastrectomy is the operation of choice. The author believes that any operation short of gastric resection and excision of the ulcer is inadequate for gastric ulcer. Either a posterior or an anterior type of Polya anastomosis, with a long loop of jejunum without entero-enterostomy is advised. A transfusion of 500 cubic centimeters of citrated blood is given during the operation.

In operations for duodenal ulcer the author prefers to excise the ulcer if it is reasonably possible and if it is a bleeding ulcer its blood supply should be securely ligated. A Finney type of pyloroplasty is quite satisfactory in certain types of ulceration with obstruction. In an elderly patient with low free hydrochloric acid and no history of bleeding, a pyloroplasty is satisfactory. In all others a gastric resection with removal of the pyloric antrum is employed by the author.

A large amount of technical detail is described. Sixteen figures, six tables and a bibliography accompany the article.

Nelson M. Percy, Chicago.

DIXON, C. F., DEUTERMAN, J. L. AND WEVER, H. M.

Diverticula of the Intestine. S. G. O., Vol. 66, No. 2A, pp. 314-327, Feb. 15, 1938.

The consensus of opinion is that diverticula of the intestine develop as herniations of the mucosa at points of entry of the veins. Supposed degeneration of venous connective tissue at those points leads to a weakness which gives way under increased pressure when other portions of the intestine contract. Meckel's diverticulum is a congenital abnormality.

Diverticula occur most commonly in the sigmoid colon and least commonly

in the ileum; about 18 per cent are found in the duodenum.

These structures when symptomless are looked upon as anatomical curiosities. In about one-fifth of the people with diverticulosis some inflammation supervenes and diverticulitis is present. Diverticulitis may lead to partial or complete obstruction of the bowel, or to perforation with abscess formation or perforation into another hollow viscus, forming an internal fistula. Meckel's, especially in children, is occasionally caused by bleeding from an ulceration in a Meckel's diverticulum.

The medical treatment of diverticulitis consists of bed rest, non-residue diet, liberal doses of belladonna and warm saline irrigations per rectum. Occasionally it is necessary to put that segment of bowel at rest by making a colostomy above the diseased part. The authors state that it was Judd's opinion that such a colostomy should not be closed before a year had elapsed.

Nine figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.

MEANS, J. H.

Treatment of Peptic Ulcer—Indications for Surgery. S. G. O., Vol. 66, No. 2A, pp. 264-268, Feb. 15, 1938.

The author states that the etiology of peptic ulcer is unknown. It is important to differentiate simple ulceration from carcinoma and to determine whether the two conditions co-exist.

Surgery is indicated when medical treatment has failed and when certain complications are present, and sometimes when previous surgical treatment has failed.

Perforation is an urgent indication for immediate surgery. Just how much should be done is a mooted question. The author is of the opinion that a single hemorrhage in a person under 45 years of age is definitely not an indication for surgery, but repeated hemorrhage may be. A hemorrhage in a person over 45 years of age may be an indication for surgery, but there is a fair chance that he may never have another hemorrhage.

Pyloric obstruction when permanent and not due to spasm or edema is an indication for surgery. Resistance to medical treatment is a weighty indication for surgery. One should make certain that the treatment has been good and under proper conditions. The more a patient's problems harass him, the more their ulcers will plague them. Any patient with peptic ulcer should be under some treatment for the remainder of his or her life.

A large bibliography accompanies the article.

Nelson M. Percy, Chicago.

Persistent Anorexia

A RECOGNIZED INDICATION FOR VITAMIN B₁

ANOREXIA is often closely connected with deficiency of vitamin B₁, which manifests itself also by reduced secretory and motor activity of the gastrointestinal tract. The patients who can be benefited by the administration of vitamin B₁ include those with a failing appetite and malnutrition and those in whom the appetite and nutrition have been impaired by an acute or chronic exhausting illness.

The importance of providing the growing child with an adequate supply of vitamin B₁ is also generally recognized.

The presence of polyneuritis in beriberi is striking evidence of the detrimental influence of marked vitamin B₁ deficiency upon the peripheral and central nervous system. Therefore, it is likely that in neuritis of obscure origin the causative factor may be B₁ avitaminosis.

CLARK, E. BROWN AND SHIELDS, WARREN.

Visceral Metastasis from Rectal Carcinoma. S. G. O., Vol. 66, No. 5, pp. 611-621, March, 1933.

The authors studied autopsy protocols of 170 patients who had carcinomas of the rectum within 15 centimeters of the anus, or who had had carcinomas removed from that region. Microscopic sections were studied in order to confirm the diagnosis and to look for tumor growth in blood and lymphatic vessels. This was difficult and in case of doubt the decision was made against intravascular invasion.

The tendency for rectal carcinoma to metastasize via the blood stream varies with the degree of differentiation. The type described by the authors as carcinoma simplex showed visceral metastasis in 56 per cent of the cases. Mucinous carcinoma has a tendency to metastasize via the lymphatics. As would be expected, the longer the duration of the carcinoma, the greater the number of visceral metastases. In only 5 per cent of the cases were metastases to bone found. Forty-one per cent of the cases showed visceral metastases; the liver being the most common site. The correlation between intravascular growth of the tumor and visceral metastases is closest in the

cases of longer duration. Visceral metastases were found in 21 per cent of the cases showing no lymph node metastases. A better prognosis may be rendered by determining the pressure or absence of intravascular growths than by determining the presence or absence of lymph node metastases.

Ten tables and a bibliography accompany the article.

Nelson M. Percy, Chicago.

LEWISOHN, R.

Segmental Enteritis. S. G. O., Vol. 66, No. 2, pp. 215-222, Feb. 1, 1932.

Segmental enteritis is at present a disease of unknown etiology. For that reason classification is difficult and proper medical or surgical treatment is not generally agreed upon. The author doubts whether segmental enteritis is a clinical entity; he feels that it may turn out to be a milder form of ulcerative colitis.

Fistulous communications between parts of the intestinal tract and symptoms of partial intestinal obstruction are prominent features in the clinical course of this disease. The author points out that peri-anal and recto-vaginal fistulas are occasionally seen also.

The treatment of this disease is distinctly surgical. Resection in one or two stages or sidetracking operations have cured the disease. If a sidetracking operation is elected, the bowel should be divided above the diseased portion and closed, insuring complete rest of that part. The presence of a fistula makes primary resection mandatory.

Six figures, one table, and a bibliography accompanying the article.

Nelson M. Percy, Chicago.

LICHTMAN, S. S.

The Association of Sciatic Neuritis with Liver Disease. Annals of Int. Med., 11:1992-1995, May, 1938.

The author reports five cases in which symptoms of sciatic neuritis preceded the onset of clinical evidence of liver damage and jaundice. In three instances the jaundice and liver disease occurred in persons who had not ingested cinchophen in any form.

These observations suggest that endogenous toxic substances, responsible for the peripheral neuritis involving the sciatic nerve, may also be responsible for the liver injury.

Hanes M. Fowler, Fort Wayne.

Decholin

REG. U.S. PAT. OFF.

THE COUNCIL ACCEPTED BILE ACID

- 1 Available in crystalline form, chemically pure...
- 2 Available in a white, compressed tablet without coating or coloring...
- 3 So low in toxicity that its sodium salt may be injected intravenously.

Decholin—c.p. dehydrocholic (triketocholanic) acid—is of established value in chronic cholecystitis, noncalculous cholangitis, hepatitis of toxic origin, biliary insufficiency. It increases

bile secretion by the liver cells 100% to 200%, and exerts a notable cholagogue influence. Contraindicated in mechanical obstruction of the bile passages.

Therapeutic Preparations for the Medical Profession

In cases of hyperacidity and peptic ulcer the use of LACTALUMINA—the original colloid of aluminum hydroxide—is suggested to control excess acidity without interfering with normal digestive processes. Supplied in liquid form in 8 oz., 16 oz. and 80 oz. bottles.

If a calf had gastric ulcers

would cow's milk
have irritative effect?

Whether it would or
not may be of no in-
terest—except that

the question directs attention to an obvious fact,
so obvious indeed that often too little thought
is given to it—and that is, that nature designed
cow's milk for the stomach of a calf—and the
large, tough curds of cow's milk usually have
irritative effect on an ulcerated stomach of a
human being.

However, all forms of cow's milk do not have
the same curd formation. Pet Milk forms very
soft, flocculent curds, having a curd tension 90%
less than that of ordinary milk. Therefore, it has

little, if any, irrita-
tive effect on the gas-
tric ulcers of patients.

Add to this desirable feature: Complete ab-
sence of bacterial life—uniform richness in the
solids of whole milk—finely divided and evenly
distributed fat globules—plus extra vitamin D
created by irradiation—and the result is a com-
bination of qualities making Pet Milk especially
suitable for the dietary treatment of digestive
diseases.

Irradiated Pet Milk costs less, generally, than
ordinary milk.

Samples and literature will be sent on request.

Carbonate Excretion in the Urine as an Indication of Alkalosis

By

LEE C. GATEWOOD, M.D.
CHICAGO, ILLINOIS

A SEARCH of the literature reveals a dearth of data concerning the presence of carbonates in the urine, Denis and Minot (1) stating "In the course of our investigation of certain problems which involved the ingestion of small quantities of sodium bicarbonate it was found convenient to use the carbon dioxide content of the urine as a measure of bicarbonate excretion. In this connection the question at once presented itself as to what variations must be looked for in the excretion of urinary carbon dioxide under ordinary normal conditions. A consultation of the literature proved unfruitful. The recorded determinations of carbon dioxide are few in number and have been made under conditions of such diversity that correlation of the various results appeared difficult, if not impossible." They made a study of carbonate excretion and as a result of their studies they reached the conclusion that the amount of carbon dioxide in the urine of subjects taking ordinary mixed diets varied from 20 to 211 cc. per 24 hours and that the amount excreted varied with the reaction of the urine. Mitchell (2) discussed the available tests for alkaline carbonates in the urine, suggesting the use of mercurous nitrate for the determination of ammonium carbonate in the urine. Later he suggested the use of nickel sulfate (3) for the demonstration of the presence of soluble carbonates in the urine.

Gamble (4) made a further study of the factors which determine the elimination of carbonic acid in urine and reached the conclusion that the bicarbonate content of urine varied inversely with the urinary pH and that the elimination of carbonic acid in the urine was determined by the CO_2 tension of the blood plasma.

A study of the disturbances of acid-base equilibrium occurring in patients on alkali therapy for peptic ulcer (5) and the urinary findings which they presented brought to our attention some unexpected variations in the amount of carbon dioxide liberated from the urine when acid was added to it in the course of the usual tests for albumen. It was observed that some alkaline specimens of urine showed very little evidence of carbonate whereas others showed considerable amounts. The use of nickel sulfate as a test for carbonates and its clinical application to the problem in hand was then begun on my service with the help of one of my former assistants, Dr. John S. Ashby, and we were thus enabled to confirm and enlarge our previous observations.

The technique of the test is very simple. Solutions of nickel sulfate in the presence of soluble carbonates precipitate a white cloud of nickel carbonate. For clinical purposes the test is most conveniently made in a conical glass into which is put a few cubic centimeters of 20% nickel sulfate solution. Filtered urine is then carefully overlaid by pouring the urine into a folded filter paper and allowing it to run gently down the side of the glass as in the familiar nitric acid test for albumen. The presence of soluble carbonate in the

urine is indicated by the formation of a white ring of precipitate at the point of contact of the two fluids. The thickness or density of the precipitate ring affords a simple means of making gross quantitative comparisons of the amounts of carbonate present in different samples of urine. The test has been found to be delicate enough to indicate the presence of small quantities of soluble carbonate in the urine, a 0.25% solution of carbonate in water yielding a positive reaction. It is suggested that those who have not previously used the test and may wish to do so, can readily familiarize themselves with it by testing specimens of urine to which known quantities of sodium bicarbonate solution has been added. The sensitiveness of the reaction varies somewhat with the reaction of the urine. In general the higher the acidity of the urine the less sensitive the reaction seems to be and its sensitiveness seems to be enhanced somewhat in alkaline urines. Specimens of urine to which a solution of sodium bicarbonate has been added have been allowed to stand for 24 to 48 hours and at the end of this time still show a typical precipitate with nickel sulfate solution.

The quantity of carbonate present in the urine of normal subjects upon a general diet is insufficient to produce a detectable ring. This has been determined by testing a considerable number of routine urine specimens with uniformly negative results.

However, the ingestion of sodium bicarbonate is followed within a short time by the appearance of carbonate in the urine in amounts sufficient to show a definite white ring of precipitate at the point of con-

TABLE I
Appearance time of carbonate in urine after ingestion of 4 gms. sodium bicarbonate

tact with nickel sulfate solution. Following the ingestion of 4 gms. of sodium bicarbonate the urine shows at the end of an hour sufficient carbonate to produce a positive reaction and this may continue to be present for as long as three hours after the ingestion of the soda though the maximum reaction is usually obtained at the end of two hours. Using phenolphthalein as an indicator there is a decrease in the acidity of the urine on titration with N/10 NaOH

corresponding to the increase in carbonate content. This is in conformity with the findings previously reported by Denis and Minot and by Gamble.

In earlier years when sodium bicarbonate was used rather generally in the alkali treatment of peptic ulcer it was found that the application of this test to the urine of such patients yielded quite regularly a positive carbonate reaction. However, upon the development of alkalosis there was as a rule prompt decrease in the excretion of carbonate to the point where this reaction could no longer be demonstrated. With return

to normal acid-base equilibrium there was a return of carbonate excretion. There is some variation in the level at which carbonate excretion disappears. In general it has been found to decrease below the level at which a positive nickel sulfate reaction can be demonstrated when the level of blood CO₂ combining power exceeds 65 volumes per cent and in only one instance has it been found to persist above a level of 70 volumes per cent. On the other hand there have been only rare instances in which carbonate excretion

was found to be materially diminished with blood CO_2 values below 60 volumes per cent.

At the time we began using this test a great many of the patients on alkali type ulcer treatment were receiving powders of which sodium bicarbonate was a component and it was, therefore, a simple procedure to test the urine of such patients with nickel sulfate. The finding of a heavy carbonate precipitate at the point of contact then provided a degree of assurance that the patient's acid-base equilibrium had not been seriously disturbed. If, however, the urine showed little or no evidence of carbonate content a blood CO_2 determination was immediately started and a change in therapy instituted.

For a number of years we have used little or no sodium bicarbonate in our program of ulcer therapy. The alkalies used, as indicated under the heading of "Medication" in the accompanying table, have been chiefly calcium carbonate, calcium phosphate, tri-basic magnesium phosphate and magnesium oxide. Occasionally we have used magnesium carbonate and more recently various preparations of aluminum hydroxide. In some instances the old combination of magnesium oxide and sodium bicarbonate has been administered for a few doses in the course of the day but the quantity of sodium bicarbonate taken in this way rarely exceeds thirty to sixty grains spread over the course of the day. It has been found that the administration of calcium carbonate in doses of 10 to 15 grains per hour as commonly used does not give rise to a positive carbonate reaction in the urine as tested with nickel sulfate. Some patients who have received larger doses of calcium carbonate have shown a positive carbonate reaction in the urine. In order to utilize this test clinically, therefore, it is usually necessary to provide a source of soluble carbonate and this may be done by giving the patient two or three doses of sodium bicarbonate instead of his usual alkali therapy. Practically, this has been done by giving the patient 30 or 40 grains of sodium bicarbonate at hourly intervals instead of the usual alkali dosage and obtaining a control specimen of urine before the first dose of soda and a specimen two hours later—one hour after the second dose of soda. Each specimen is tested with nickel sulfate solution. An individual with normal acid-base equilibrium will show, as a rule, no precipitate or only a trace in the control specimen and a definite carbonate ring in the second specimen.

In the accompanying table are shown records of a number of tests performed in this manner. The data therein presented are selected from the records of approximately one hundred cases in which this test has been used. Naturally most of these patients did not at any time present manifestations of alkalosis and the nickel sulfate reaction yielded a simple normal response. It has not seemed essential to multiply the presentation of such cases though a few typical examples are recorded in the table. Attention is called rather to those cases which present disturbance of acid-base equilibrium and to the corresponding urine test with nickel sulfate and particularly to those patients presenting normal carbonate secretion with blood CO_2 combining power within normal range and deficient carbonate excretion in periods marked by alkalosis.

It is manifestly undesirable to administer sodium bicarbonate for this test if the patient already presents findings such as to constitute a strong presump-

tion of alkalosis. There are found occasionally abnormalities of carbonate excretion which are not on the basis of alkalosis. For example some patients with nephritic nitrogen retention and consequent acidosis have shown deficient carbonate excretion. The test has been applied in several such cases and with some patients with cirrhosis and ascites who have been converted to a state of acidosis by the administration of ammonium chloride but the data available are thus far insufficient to warrant conclusions. The information available from this test is certainly not as accurate or conclusive as that from blood carbon dioxide determination and it is not proposed as a substitute therefor. It is, however, a very simple test to make, inexpensive and not time consuming. Since it has been found that there is relatively little change in the carbonate reaction of such urine specimens on standing and such specimens are readily transportable this test has occasionally proved valuable as an indication of acid-base equilibrium in patients who were located in places too remote for readily available blood CO_2 determination.

CONCLUSIONS

1. Nickel sulfate has been found a convenient reagent for the demonstration of soluble carbonate in the urine.

2. Patients who are taking sodium bicarbonate or other soluble carbonates excrete demonstrable amounts of carbonate in the urine as shown by this test.

3. In a state of alkalosis the carbonate excretion is markedly decreased or absent. With return to a normal acid-base equilibrium there is a return of normal carbonate excretion.

4. This test by reason of its simplicity and its applicability to transportable urine specimens presents a field of usefulness where, for various reasons, determinations of blood CO_2 combining value or pH are not available.

I wish to acknowledge the help of Dr. John S. Ashby and Dr. Mary Christine Gatewood.

DISCUSSION

DR. WALTER G. KARR (Philadelphia, Pa.): I believe Dr. Gatewood has emphasized a very important point in the acid-base balance of the body. We know that the kidneys have a large factor of safety. When acids are presented they manufacture ammonium salts. The phosphate buffer controls the acid base balance in the urine between pH 5 and 8. We have believed that the excretion of sodium bicarbonate directly by the kidney was a very efficient mechanism in regulating alkalosis. We have believed that mechanism was rather unlimited and with a good urine output the kidney could easily control almost any alkalosis; however, Dr. Gatewood has indicated quite definitely here that there seems to be a limit in many cases around 65 to 70 vol. per cent. plasma CO_2 , above which bicarbonate is not secreted in the urine.

This is rather a new idea and it explains to a large extent these cases of alkalosis which have appeared in the past, when bicarbonate therapy was more in general use. I believe about 5 per cent of those cases usually showed the signs of toxicity that you all know.

It is perhaps worth while to differentiate between this alkalosis which is definitely an alkali excess, and that alkalosis which occurs with a total electrolyte or total base loss from the body and originates with pernicious vomiting. We have in those cases a low total electrolyte in the body and it would be interesting to know if those cases respond in the same way as these cases with alkali excess.

It is obvious that in an acidosis, where the secretion of CO_2 is of necessity very low, this test will probably be negative. I believe that this work is an indication for a great deal more study of the acid-base mechanism in an experimental way. The mechanism of this alkalosis should be re-studied all the way through by animal experimentation.

Certain pathologists have talked about an alkalosis kidney, which I know absolutely nothing about, but undoubtedly that is related to the same condition.

DR. VICTOR C. MYERS (Cleveland, Ohio): I should like to ask a question of Dr. Gatewood. I do not recall that he explained why the carbonate excretion in the urine should be decreased or absent in alkalosis. It has been recognized for sometime that with a constant alveolar CO_2 tension there is a definite relation between the pH of the urine and its bicarbonate content, and that the bicarbonate content of the urine at a pH of 8 is ten times that of pH 7 and 100 times that at pH 6. In simple terms the bicarbonate increases with the alkalinity of the urine.

Even the CO_2 of the blood is not always an absolutely reliable indication of alkalosis. There may be some little

fluctuation in the CO_2 around the critical level without a change in the pH of the blood plasma. I have seen a high blood pH and clinical symptoms of alkalosis with a plasma CO_2 of 56 vol. per cent while on the other hand I have seen the plasma CO_2 rise to 70 vol. per cent before the pH of blood became abnormal. About eleven years ago Dr. Gatewood's brother and I reported a paper before this Association in which we called attention to a number of points dealing with chemical blood findings in relation to sodium bicarbonate administration and clinical symptoms of alkalosis.

It would seem to me that this test of Dr. Gatewood's should be of considerable usefulness if it obviates the need of much more complicated laboratory procedures.

Variations in the Enzymatic Activity of Duodenal Contents*

Preliminary Report

By

VICTOR C. MYERS, Ph.D., D.Sc., ALFRED H. FREE, M.S.

and

ARGYL J. BEAMS, M.D.

CLEVELAND, OHIO

SINCE the introduction of the duodenal tube by Einhorn (1) in 1910 the estimation of the enzymatic activity or concentration of duodenal contents has received the attention of many gastro-enterologists and scientists in allied fields, and a considerable literature has accumulated on the subject. A marked reduction in enzyme activity has been observed in pancreatitis, while some reduction in the activity of the pancreatic enzymes has been noted in a variety of disorders, chiefly those which might have some influence on the pancreas. That no unanimity of opinion exists as to the most desirable methods to employ in measuring these enzyme activities is evidenced in the survey which was conducted by this Association (2) four years ago. Some of the methods employed have been hardly more than qualitative tests, while others, notably those of McClure and his co-workers (3) have yielded fairly reliable quantitative information on the concentration of the enzymes. The interest of one of us (M.) in this subject was revived due largely to a request to cooperate in the study of enzyme methods.

We fully appreciate the difficulty in making a significant contribution to a problem that has been studied repeatedly. We have felt, however, that with further refinement in methods, taking due account of the various factors involved in measuring the activity

of the duodenal enzymes, it should be possible to define normal values more accurately than has been done in the past.

The first purpose of the work we are reporting was, therefore, to establish a system of analysis which would give an accurate picture of enzyme activity. We believe that the methods which we have worked out do yield such data. It seemed essential that the methods should employ optimum conditions for the activity of the enzymes, including optimum pH, optimum buffer concentrations, optimum substrate concentrations, and should be based on the measurement of digestion products, rather than on the disappearance of the substrate. The principles underlying the methods we have used are not new, but we believe that adherence to certain exact details, and a new scheme of recording the results permit a more accurate definition of normal variations and thus an earlier recognition of pathological values.

It seemed necessary at the outset to ascertain for ourselves the optimum pH for the action of the protease, lipase and amylase of duodenal contents. If possible, we wished to employ the same buffer solution for all these enzymes. The buffer phosphate solution of pH 8.4 employed by McClure (3) and his co-workers seemed too high to us, considering the average pH of duodenal contents. As a matter of fact, we found relatively little difference in the proteolytic action on casein over a pH range of 6.8 to 8.4 and in the lipolytic action on tributyrin and triolein over a pH range of

*From the Departments of Biochemistry and Medicine, School of Medicine, Western Reserve University and the Medical Clinic of Lakeside Hospital, Cleveland, Ohio.

7.0 to 8.4. However, in the case of amylase the enzyme activity was definitely greater at a pH of 7.2, the sodium chloride concentration being held at the optimum of 0.05 M. This observation was of interest to us in connection with the fact that, although the pH of duodenal contents fluctuates over quite a wide range, from a pH of about 4.0 to more than 8.0, the average appears to be just on the alkaline side of pH 7.0. On this basis a buffer phosphate solution of pH 7.2 was employed in all our work on duodenal enzymes.

The principles of the methods developed for the estimation of the proteolytic, lipolytic and amylolytic enzymes in duodenal contents will be briefly outlined in an effort to visualize the technique we have employed. As indicated above the end products of digestion were used in each case as the measure of enzyme activity, viz., amino acid nitrogen for protease, fatty acids for lipase and reducing sugar (maltose) for amylase.

Protease Method. The method for protease (trypsin) was similar to that employed by McClure (3). We were unable to find a better protein for the substrate than casein. A number of different preparations of casein were tried and all found to be satisfactory. As noted above the pH was buffered at 7.2. After digestion for 30 minutes at 38° C. the residual casein was precipitated with trichloroacetic acid and the non-protein nitrogen determined in the filtrate. This was done colorimetrically with the aid of Nessler's solution after kjeldahl digestion of the filtrate.

In all experiments a measured portion of the filtrate was also treated with Folin's phenol reagent in a manner similar to that employed by Anson and Mirsky (4) in their method of estimating trypsin, using hemoglobin as the substrate. Almost identical results were obtained with the two methods. It would therefore make little difference which procedure was employed to obtain the final result.

Lipase Method. Two methods have been employed in the estimation of lipase, one in which tributyrin was used as the substrate and the other in which an emulsion of triolein was used. The latter is the method described by Crandall (5), with slight modifications. The procedure is the same with both methods after incubation. Neutralized ethyl alcohol is added and titration carried out with 0.1 N NaOH in 95 per cent ethyl alcohol using phenolphthalein as the indicator. Essentially the same results were obtained with both methods.

Objections have been raised to the use of tributyrin as a substrate for lipase determinations on the basis that it measures an esterase system rather than a lipase system. On the other hand it is generally conceded that true lipase attacks triolein (or olive oil). However, the preparation of a suitable olive oil emulsion offers certain technical difficulties. In our studies optimum buffer concentrations as well as pH and enzyme concentrations were established. The two methods gave comparable results in over two hundred specimens studied and no instances were noted where the interpretation of the results would be any different with one method than the other. Therefore if there are two distinct enzyme systems, a lipase and an esterase, they parallel each other and give similar results. Neither of the methods give a perfectly straight line relationship, such as is obtained with trypsin and amylopsin, but there appears to be a good relationship between the titration figures and the amount of enzyme present.

Amylase Method. The method employed for amylase (amylopsin) was a modification of the method introduced by Myers and Killian (6) to measure the diastatic activity of blood. As a matter of fact they also employed the method for duodenal contents. As already noted amylase is quite sensitive to pH when optimum concentrations of activating sodium chloride are used. The method was worked out to provide optimum pH (7.2) along with optimum NaCl concentration. A plicate method was used to estimate the maltose formed. As shown by Myers and Reid (7) this method is much more satisfactory than the Folin-Wu method for this purpose. Soluble starch was used as the substrate and several different preparations were found to be satisfactory. The method as employed gave an almost perfect straight line relationship, i.e., the amount of reducing sugar formed was directly proportional to the concentration of amylase over the range of enzyme concentrations found in human duodenal contents.

Duodenal contents were obtained in the usual manner with the aid of a Rehfuess tube, the position of the tube being checked in practically all cases with the fluoroscope. It soon became apparent that the fasting duodenal contents were quite irregular in enzyme activity. In all cases reported four samples of fluid were collected, all of which were analyzed, a total of considerably more than a 1000 determinations being made. A 20 minute fasting sample was obtained by siphonage following which 25 cc. of olive oil were injected through the tube into the duodenum. Ten minutes were allowed to elapse and then continuous siphonage established. The samples were divided into three fractions each representing the drainage over a 20 minute period. In addition to the enzymes, the icteric index was determined on all samples to obtain an idea of the amount of bile present, and the buffer value also determined on the fasting sample. The volume was also recorded so that the total enzyme output as well as the concentration could be calculated, if desired.

A group of 13 studies has been carried out according to the technique described on 9 normal individuals, including both sexes. In general the highest enzyme values were found in the 3rd or the 2nd specimen after stimulation with the olive oil, although this was not always true, and occasionally the highest value was found in the 1st or fasting specimen. At present it has seemed unwise to limit the analyses to one specimen, and the four specimens have all been analyzed. We are hoping ultimately to obtain a sufficiently potent pancreatic stimulant to make the analysis of more than one sample unnecessary.

For the present we are selecting as the criterion of potential enzyme activity the maximum value obtained in the four samples. This has been found, with but few exceptions, in the 3rd or 2nd sample. It is on the basis of this series of values that we wish to suggest a range of normal values, and a method of expressing the values that can be readily understood. We realize that our series of normals is small at present, and we plan to extend the number before finally publishing our results. The analytical data obtained for an enzyme represent the activity of the enzyme but not the enzyme itself, and it seems more logical here than elsewhere to arbitrarily take 100 as the normal. If one averages the findings for each of the three enzymes and assumes that this average is 100 per

cent, it is simple to calculate a factor by which all other values may be expressed in terms of 100 per cent. (As will be noted in Slide 6), the normal range of activities was found to be from 45 to 151 per cent for protease, 72 to 126 per cent for lipase and 56 to 169 per cent for amylase.

In a group of 11 cases suffering from miscellaneous gastro-intestinal disorders it was noted that a number gave slightly subnormal values, suggestive of reduced pancreatic activity.

The question has frequently been raised as to whether or not the external secretion of the pancreas was affected in diabetes. The most complete study in this regard was that by Jones, Castle, Mulholland and Bailey (8) in 1928. They studied 68 unselected diabetics and found the pancreatic enzymes diminished in nearly half the cases, the greatest alterations in enzyme activity being noted in the lipolytic and proteolytic ferments. On the other hand in the discussion of enzyme methods 4 years ago (2), Dr. Crohn stated with regard to this same problem: "My own experience is dimetrically opposite. I have always found increased pancreatic secretion in diabetes." We have made observations on 8 diabetics. Comparatively low values were obtained in 7 cases, the values for protease, being lower than those for lipase and amylase. On the other hand one case showed higher values than any we have observed in our normal group. It might be noted that most of these cases complained of abdominal distress.

Observations were made on four cases showing definitely low activities for all three enzymes. These were diagnosed as chronic pancreatitis, sprue, epigastric pain and severe diarrhea. In the fourth case the diagnosis was not clear. There can be no doubt about the reduced activity of the pancreatic ferments in these four cases. The average of the four cases showed the activity of the three enzymes in comparison to normal to be: protease, 19 per cent; amylase, 20 per cent; and lipase, 50 per cent.

Time does not permit a discussion of the relation of bile to enzyme activity, although it might be noted that in general a high bilirubin content and good enzyme activity appear to go hand in hand. However a few specimens were encountered with good enzyme activity in the absence of bile.

CONCLUSIONS

A system of enzyme analysis has been developed which permits an accurate estimation of the proteolytic, lipolytic and amylolytic activity of the enzymes of duodenal contents. When this system of analysis is applied to duodenal contents secured after stimulating pancreatic secretion with olive oil, it has been found possible to define the normal range of values with a reasonable degree of accuracy, and give these in terms of the normal taken as 100. Employing this method of recording the enzyme activities to pathological cases, abnormal values stand out very clearly from the normal. Very low values are found in pancreatitis and certain other conditions, while subnormal values are encountered in various gastro-intestinal disorders which may have an effect on the pancreas. In diabetes the enzyme activity may be subnormal, or considerably elevated.

DISCUSSION

DR. ANDREW C. IVY (Chicago, Ill.): This is a piece of work which I personally have been very glad to find has been done by Dr. Myers and his colleagues. Before we can pass judgment on these methods, we shall have to use them ourselves and find out how accurate they are in our hands and how applicable they are as far as diagnosis is concerned.

We have many methods for enzyme determinations in the literature and some workers use some of the methods and other workers use others. As to whether Dr. Myers' methods will be suitable depends upon how we use them, and that will be the practical test of these methods: Will you use them?

DR. THOMAS R. BROWN (Baltimore, Md.): May I be permitted to ask Dr. Myers three questions?

In the first place, has he noted that the rise and fall of these three enzymes has always been parallel, as it were? Has he recognized the fact that most people feel this is true, and, therefore, would it be practical to determine only one of the three?

In the second place, has he done any work in comparison with these and comparative methods of quantitative estimates of enzymes in the stools?

In the third place, has he noticed, as I have done in work a good many years ago, there was often absence of these ferments in carcinoma of the head of the pancreas, while in certain cases of sprue and chronic pancreatitis, the figures are low?

In certain of my cases of sprue I had almost complete absence of them. I am singularly interested in his opinion of the first of these; in other words, do these ferments rise and fall together, or is there evidence that certain of these three rise and fall more than the others.

DR. HARRY SHAY (Philadelphia, Pa.): I should like to ask Dr. Myers how reproducible his results were on repeated occasions with the same patient. I wonder whether he noted that he obtained more closely reproducible results in his fractions after the olive oil stimulation than he was able to do in the fasting specimen.

The reason I bring this up is that I suspect that the latter may be the case. We have shown in our gastric motor studies that the effect of the tube through the duodenum does not influence gastric emptying. Because of this, the fasting specimen could be more frequently modified by gastric contents coming through the pylorus into the duodenum than would be the case after the addition of the olive oil to the duodenal contents, such an addition resulting in pyloric closure.

DR. VICTOR C. MYERS (Cleveland, Ohio): I wish to thank Dr. Ivy for his comment. With regard to the methods, we have used two methods in the case of protease and two in the case of lipase. I do not believe that if one uses the scheme of nomenclature that we employed—I do not know that I was able to say enough about this—it is going to make very much difference what method one uses, provided the method is properly carried out, and there is a straight-line relationship between the enzyme concentration and the end products formed.

I should like to repeat the statement about the scheme of nomenclature: "The analytical data obtained for an enzyme represent the activity of the enzyme but not the enzyme itself, and it seems more logical here than elsewhere to arbitrarily take 100 as the normal. If one averages the findings for each of the three enzymes and

assumes that this average is 100 per cent, it is simple to calculate a factor by which all other values may be expressed in terms of 100 per cent."

Now, as was noted on Slide G, to which I called your attention, the normal range of activities in the case of protease was found to vary between 45 and 151 per cent, between 72 and 126 per cent for lipase and between 56 and 169 per cent for amylase in our thirteen subjects. We hope to have a larger series of normals before we finally publish our observations.

It wouldn't make any difference, with this scheme of nomenclature, what method you used provided it was suited to the purpose. It seems to me this is a good way to express enzyme values because a medical man not so familiar with laboratory procedure can recognize 100 as a normal and deviations from the normal on this basis.

With regard to Dr. Brown's question, we did do fractional analyses and we do have simultaneous determinations, but it didn't seem practical to present all the observations at this time. The values for the three enzymes parallel each other fairly well, and if the duodenal con-

tents have a high content of bile (bilirubin) the agreement is quite good. However, the agreement between the three enzymes is not perfect. If one were to limit the determination to one enzyme, I would say to put protease first, amylase second, and lipase third. We have not done any determinations on stools. However, I would feel that work on duodenal contents was a great deal more definite and helpful than it would be on stools.

With regard to Dr. Shay's question, there is no doubt we get more constant values after the use of olive oil. Occasionally we have found the highest figure in the fasting specimen, but this is the case only infrequently. There is no doubt but what it is better to use the fluid collected after olive oil, since the enzyme concentrations are relatively more constant.

We have been hoping to get a better pancreatic stimulant and take one specimen after that stimulant and perhaps simply determine the protease on this specimen. However, the amylase and lipase estimations do give confirmatory and sometimes additional information.

The Triple Mechanism of the Chemical Phase of Gastric Secretion*

By

B. P. BABKIN, M.D.
MONTREAL, CANADA

THAT besides the first, or "nervous," phase of gastric secretion there is a second, or "chemical," phase, is evident from the fact that food substances or the products of their digestion, on introduction into the denervated stomach or into an isolated and denervated pyloric pouch, provoke secretion of the glands of the fundus and corpus of the stomach. The chemical phase again is divisible into two parts, the "pyloric" and the "intestinal," because the gastric glands may be stimulated by the introduction of food substances into the pyloric region of the stomach or into the small intestine.

I. THE PYLORIC CHEMICAL PHASE

More than thirty years ago Edkins (1906) claimed that under the influence of certain substances present in the food the pyloric mucosa elaborates a special and specific hormone, which provokes gastric secretion, and which came to be known as "gastrin." That such a hormone occurs is highly probable, but what its true nature may be is a matter of great controversy.

Some of the facts which seem to indicate that gastric secretion during the pyloric phase is under hormonal control are as follows: (1) The very limited absorptive power of the gastric mucosa. No proteoses, peptone, starch or fat are absorbed by the stomach. Only monosaccharides and amino-acids, *i.e.* substances which are very seldom or never present in the stomach, may pass through the gastric mucosa and enter the circulation (Delhouge, 1931). (2) Soap solutions and solutions of acetic acid, on being introduced into an isolated pyloric pouch elicit a copious gastric secretion from the stomach (Sawitsch and Zeljony, 1913). It is very doubtful that these substances as such are ever present in the blood. Moreover Zeljony (1912) showed

that the introduction of soap solution into the intestine, from where it may be absorbed, does not provoke secretion in the stomach when the latter is isolated from the duodenum. (3) The previous application of atropine or cocaine to the mucosa of a pyloric pouch prevents stimuli that are introduced into the pouch from exerting a secretory effect, presumably by delaying or preventing the formation of a gastric hormone. (4) Extracts of liver or meat provoke gastric secretion not only when injected intravenously but also when applied locally to the gastric mucosa. The minimal amount of liver extract necessary for the stimulation of gastric secretion by local application was found to be one-quarter of that required for the production of an equivalent secretion by intravenous injection (Kim and Ivy, 1933). This shows that the last-mentioned secretagogue produces its effect in some other way than through being absorbed.

It is not possible to discuss here the voluminous literature concerning the nature of the gastric secretory hormone. (Those interested in the problem may consult Babkin (1928) and Ivy 1930, 1931)). The results obtained by various investigators may be briefly summarized, as follows. One group of workers, as representative of whom may be quoted Luckhardt, Keeton, Koch *et al* (1915-1920), established the fact of the striking similarity between "gastrin bodies" and histamine, and expressed the view that these are similar and even perhaps identical chemical entities. According to them, the "gastrin bodies" can be extracted from the whole gastric mucosa and part of the intestinal mucosa, as well as from some other organs. A second group of investigators, who include Ivy and his co-workers (1932, 1937), are inclined to consider histamine as a gastric secretory hormone, having isolated it and identified it chemically. The other possibilities envisaged by these workers are either that

*From the Department of Physiology, McGill University.
Read at the Meeting of the American Gastro-Enterological Association,
Atlantic City, N. J., May 2, 1935.

there is no gastric hormone or that it has never been extracted from the pyloric mucosa. A third group, namely Rasenkow (1925) and his students, maintain that there is no gastric secretory hormone, but that the food substances or the products of their digestion act on the gastric glands directly after they are absorbed. Although this point of view is probably correct in respect of the action of the food substances in the small intestine, it does not apply, as was shown above, to the mechanism of the pyloric chemical phase of gastric secretion.

In view of this state of affairs Dr. S. A. Komarov of our laboratory was prompted to reinvestigate the "gastrin" problem. He approached it from another angle than did his predecessors. Instead of extracting the non-protein substance or substances from the pyloric mucosa and trying to eliminate the protein fraction as much as possible, he concentrated his efforts on isolation of that fraction, on the analogy that the powerful and indisputable hormone of the pancreatic gland—"secretin"—is a protein-like body, although differing markedly in composition from ordinary proteins. (Thus, for example, the crystalline secretin prepared by Hammarsten and his co-workers (cf. Agren, 1934) has a molecular weight of 5000, and gives a positive biuret, but a negative ninhydrin reaction. It is a body of basic character, and contains arginine and histidine but no cystine, tyrosine or tryptophan. According to Agren and Hammarsten (1937), it is digested by aminopeptidase).

Briefly Dr. Komarov's method consisted in the following. The mucous membrane of the pyloric part of the dog's or hog's stomach was boiled in 10 volumes of $n/10$ HCl and partially neutralized with $n/NaOH$ so that it remained only slightly acid to Congo. After cooling and centrifuging of the extract, the supernatant fluid was filtered through cotton wool and precipitated with 10 per cent crystalline trichloroacetic acid. A flocculent precipitate was formed. The whole was centrifuged and the precipitate washed three times with 40 to 50 volumes of 10 per cent solution of trichloroacetic acid in saline, twice with 50 volumes of acetone, once with benzene and twice with ether. It was then dried *in vacuo*. For intravenous injection such preparations were extracted with saline at 40° C. and rendered slightly acid with HCl or slightly alkaline with Na_2CO_3 . When tested biologically (Best and McHenry, 1930; Barsoum and Gaddum, 1935) they proved to be histamine-free. This method was based on the assumption that the pyloric mucous membrane, as mentioned above, may contain a substance similar in chemical properties to secretin, i.e. a heat-stable body, soluble in aqueous or saline solution having a slightly acid reaction, precipitable with trichloroacetic acid and insoluble in a large excess of acetone or ether. In other words, it was supposed that the pyloric hormone could be obtained by methods used with great success for the extraction of a vasodilating-free secretion from the intestinal mucosa (e.g. Still's crude secretin, cf. La Barre, 1936, p. 47 ff.). These suppositions proved to be correct. In all cases, i.e. in anesthetized cats or in unanesthetized dogs with permanent gastric fistulae, intravenous injection of the pyloric extract provoked secretion of gastric juice. In the latter case it did not produce any undesirable side-effects such as nausea, salivation, vomiting, movement of the bowel, etc. Even an amount of extract equivalent to 5 gm. of pyloric mucosa elicited a copious

gastric secretion. By means of repeated injections the secretion was prolonged in one of the experiments on an anesthetized cat for 5 hours. Injection of the extract did not lower the blood pressure, presumably because it contained no histamine or choline. Atropine did not abolish its secretory effect. Usually the pyloric extract produced a very small pancreatic secretion and increased the bile flow a little. The active property of the extract was chiefly contained in the pyloric mucosa, because fundic preparations did not provoke gastric secretion, though they had a slight secretory effect on the pancreas. Extracts of duodenal and jejunal mucosa produced a copious pancreatic secretion, but only the former evoked a secretory response from the gastric glands and that was but slight. The gastric juice secreted in response to the administration of the pyloric extract possessed high acidity and very low peptic power. This shows that the extract stimulated the parietal cells almost exclusively.

The finding that an active chemical body with almost specific secretagogue properties may be extracted from the pyloric mucosa is undoubtedly a step forward in our knowledge of the factors which possibly regulate gastric secretion during its pyloric chemical phase. However, we are not yet entitled to say that the substance extracted by Dr. Komarov from the pyloric mucosa is the hormone of this phase, because we are still ignorant of the mechanism of its liberation during gastric digestion and its transportation by the blood to the gastric glands.

II. SECRETAGOGUE EFFECT OF SOME FOOD SUBSTANCES, AND OF SOME OF THE PRODUCTS OF THEIR DIGESTION OBTAINED FROM THE SMALL INTESTINE

It was established long ago by Pavlov (see Babkin, 1928) that many different substances, when introduced through a fistula into the duodenum after it has been separated by operation from the stomach, provoke gastric secretion in dogs. The same effect is produced by feeding, in dogs with the stomach completely isolated and the esophagus connected with the duodenum (Frouin, 1922; Ivy, Lim and MacCarthy, 1925). This represents the so-called "intestinal phase" of gastric secretion. There are some indirect indications which seem to show that chemical substances, acting from the duodenum, stimulate the gastric glands not by liberation of a special hormone but after their absorption. For example, there is the fact of the very long (1- to 3-hour) latent period of gastric secretion when activated by such a method (Ivy, Lim and MacCarthy, 1925; Webster and Armour, 1932, and others), as well as the effect of atropine, which temporarily inhibits the gastric secretion but does not diminish its total volume (Webster and Armour, 1932). Many of the substances absorbed from the intestine stimulate the secretory cells of the secretory gland directly, but some of them are probably acting on the secretory cells through the local nervous plexuses.

Each of the three principal groups of food substances acts on the gastric glands in a different way.

(1) *Protein*. Peptone and hydrolysed protein act as secretagogues via the intestine. Subcutaneous injection of hydrolysed protein was ineffective. Those amino-acids which stimulate gastric secretion also act as secretagogues via the intestine (for literature, see

Ivy, 1930, and Cowgill and Smith, 1933). The extractive substances of meat, when introduced into the duodenum or the small intestine, provoke gastric secretion. It is not known, however, exactly what fraction of the extractive substances exerts the secretagogue effect (*cf.* Babkin, 1928, p. 255). Among the nitrogenous bases contained in extracts of fish muscle, it was found that the arginine-histidine and lysine fractions exerted a secretagogue effect. The effect of the former fraction was much stronger than that of the latter. Since the nitrogenous bases were introduced into the stomach, it is not known exactly from what part of the gastro-intestinal tract they acted (experiments of J. Campbell—see Babkin, 1934). A number of amines which may be formed in the intestine from amino-acids stimulate gastric secretion (Ivy and Javois, 1925).

(2) *Fat.* It is well known that the action of fat on the gastric glands has two phases: an inhibitory and an excitatory. During the inhibitory phase the nervous mechanism of gastric secretion is chiefly affected, so that under certain conditions a dissociation of the functional properties of the gastric glands may be achieved (Alley, MacKenzie and Webster, 1934). Thus the production of the fluid and acid of the gastric juice in certain cases may be diminished very little, while its peptic power is greatly reduced. From a practical point of view it is important to note that a diet rich in fat, administered over relatively long periods of time, may induce a hyper-secretory condition of the gastric glands, coupled with almost complete paralysis of the vagal "trophic" action. In experiments carried out in this connection on a dog, fat was introduced directly into the duodenum, which had been separated from the stomach (Alley, MacKenzie and Webster, 1934).

(3) *Carbohydrate.* Glucose solutions, on introduction into the stomach, elicit a very scanty secretion of gastric juice. When added to other stimuli glucose greatly increases the concentration and total output of pepsin, although the volume of the secretion is somewhat diminished. The increased discharge of pepsin under the influence of glucose is especially noticeable when the effect of glucose is combined with the secretagogue effect of alcohol (experiments of Dr. M. H. Friedman, in this laboratory). Alcohol is a stimulus which activates a flow of gastric juice extremely poor in pepsin. When the special effect of glucose (60 gm. of glucose in 200 cc. of water administered by mouth to a dog with a Heidenhain pouch) was added to the secretagogue effect of alcohol (200 cc. of 5 p.c. ethyl alcohol given per rectum), the concentration and total output of pepsin rose considerably.

Choline and lecithin. Since choline and lecithin are widely distributed in food stuffs, their effect on the secretory activity of the gastric glands is of special interest. It was known that the introduction of choline into the gastro-intestinal tract stimulates gastric secretion (Ivy and Javois, 1925). In our laboratory Dr. MacIntosh and Dr. Krueger (1938) analyzed the effect of choline as well as that of lecithin in this respect. Choline, when introduced into the stomach in comparatively large doses (0.5 to 1.0 gm. in 50 cc. of water) evokes a scanty secretion of gastric juice of very low acidity but very rich in pepsin. The latent period of the secretion was about one hour, which

indicates that the substance acted not from the stomach but from the intestine. A dose of 6 gm. of lecithin, which is equivalent to 1 gm. of choline, produced an effect in all respects analogous to that of choline. The latent period of the gastric secretion was, however, twice as long as in the case of choline, which was evidently due to the time required for the liberation of choline from lecithin in the intestine. On choline or lecithin being added, the secretory response to a standard meal was increased. This augmentation of the secretion after a single dose of choline lasted for two to three days, gradually diminishing. Therefore this was the result not simply of a summation of the secretagogue effects exerted by choline and food substances, but of an increased excitability of the gastric glands. The average augmentation of the volume of the gastric secretion, after the preliminary introduction into the stomach of 1 gm. of choline and 6 mg. of lecithin respectively, was on a standard meal of meat 84 per cent and 44 per cent, on butter 130 per cent and 140 per cent. There was, however, no increase in the volume of the gastric secretion on a standard meal of white bread after lecithin administration. The output of pepsin was not essentially increased in these experiments.

The data of MacIntosh and Krueger are of great importance from the dietetic standpoint. Although in the various tissues, *e.g.*, in muscle, there is only a small amount of free choline, the total amount of choline is rather great. Thus liver contains 2300 mg. per Kg., beef muscle 760 mg. per Kg., pancreas 2300 mg. per Kg., and so on (Fletcher, Best and Solandt, 1935). This choline is quickly liberated by post-mortem autolysis, and may be present in commercial meats. Lecithin, when hydrolysed by the digestive ferments, liberates choline (Bergell, 1901), and hence may act on the gastric glands in the form of choline.

The presence of choline in food substances first of all may possibly provide a partial explanation of the well known fact that the gastric juice of the second phase of gastric secretion is richer in pepsin than that obtained through the administration of histamine or "gastrin," which stimulate almost exclusively the parietal cells. Another important fact that may perhaps be explained by the presence of choline in different food substances is the varied response of the gastric glands of one and the same animal at different times to a standard test meal. By means of special diets it is possible to raise or lower the general excitability of the gastric secretory apparatus, so that the same food will produce a different secretory effect. In this connection the experiments performed in Professor I. P. Rasenkov's laboratory may be quoted (Koschtojan, 1929; Iwanow, 1929, Tschebischewa, 1929). The effects of various alimentary regimes of long (30 to 60 days) duration on the response of the gastric glands to standard test meals, were studied in dogs equipped with a Heidenhain or a Pavlov pouch. The dogs were placed respectively on diets of meat, carbohydrate (cabbage soup, potatoes, dark bread, salt), fat (butter and dark bread), milk and bread, or mixed food. It was found that the response of the gastric glands to standard test meals of meat, bread or milk was $1\frac{1}{2}$ to 3 times greater when the animals had been on a meat or fat-containing diet than when they had been on a predominantly carbohydrate diet.

Thus it was shown that by the selection of a suitable diet the secretory activity of the gastric glands could be influenced.

III. DIRECT EFFECTS OF HYPOGLYCEMIA AND OF CERTAIN SUBSTANCES IN THE CIRCULATING BLOOD ON THE VAGAL SECRETORY CENTER

After somewhat contradictory initial reports on the effect of insulin on gastric secretion, it was finally established in experimental animals and in man that subcutaneous, intramuscular or intravenous administration of insulin provokes secretion of gastric juice. (For reviews of the literature, see Roholm, 1930; Ivy, 1930; La Barre and de Cespédès, 1931 a; Boldyreff and Stewart, 1932 a and b; Okada *et al.*, 1929, 1930, 1933; Welin and Frisk, 1936, and others). 45 to 60 minutes after intravenous injection of 2 to 10 units of insulin in a dog, or 12 to 20 units in a man, gastric secretion appears or if it is in progress is increased. In such cases, the onset of gastric secretion in man coincides with a slight general insulin reaction and with a fall of the blood sugar concentration, which in different subjects may be reduced to between 34 and 68 mg. per cent (Roholm, 1930; Welin and Frisk, 1936). Intravenous injection of a strong solution of glucose in various quantities in the dog or in man prevents or arrests the effect of insulin (Roholm, 1930; La Barre and de Cespédès, 1931 b; Okada, 1933). The statement of Boldyreff and Stewart (1932 b) to the contrary is not convincing, because the amount of glucose (15 cc. of 20 per cent solution) by intravenous injection of which they attempted to counteract the secretory effect of insulin was probably not sufficient to raise the blood sugar concentration in their animals (see Table II of their paper). In cases of diabetes where the blood sugar is high insulin is ineffective, but if the blood sugar is lowered sufficiently by a therapeutic dose of insulin adequate for a given patient, an additional dose of insulin will lower the blood sugar below the normal level and provoke gastric secretion (Meyer, 1930). Therefore, Roholm (1930) was justified in considering the gastric secretion elicited by insulin as a hypoglycemic symptom, produced by the fall of the blood sugar concentration.

The amount of gastric juice secreted by the human gastric glands in response to insulin administration varies between 100 and 200 cc. Its free and total acidities and its concentration of total chloride are high (Welin and Frisk, 1936). The pepsin concentration of "insulin" gastric juice in the dog and in man is high (Roholm, 1930; Boldyreff and Stewart, 1932 b; Dr. D. R. Webster in our laboratory—unpublished results). Much more mucus is secreted by the stomach of man after insulin, than after histamine administration (Welin and Frisk, 1936). Atropine abolishes the secretion provoked by insulin. Section of the vagus nerves also abolishes the secretagogue action of insulin, whereas it does not prevent histamine from producing its usual effect (Okada *et al.*, 1929; La Barre and de Cespédès, 1931 c, Webster—unpublished results). All these data indicate that insulin, or rather a hypoglycemic state of the blood, stimulates not the peripheral parts of the gastric secretory apparatus, but the centers of the parasympathetic system in the brain. La Barre and de Cespédès (1931 d), in fact, demonstrated this by means of the cross-circulation method of Heymans, using two dogs.

One dog, which was equipped with a gastric fistula, and the head of which was connected with the rest of its body only by the vagus nerves in the neck, received blood from another dog. Injection of insulin in the latter, which resulted in hypoglycemia, provoked the secretion of a highly acid gastric juice in the former.

Although the reduction in the blood-sugar concentration which follows insulin administration, while sufficient to provoke gastric secretion, may be not at all great, reaching approximately 68 mg. per cent (Welin and Frisk, 1936), it can hardly occur in quite normal persons. However, such conditions have been observed in cases of hypoglycemia of spontaneous type, so-called hyperinsulinemia, as reported by some clinicians (*cf.* Harris, 1935). Again, injection of a large amount of glucose, resulting in a state of hyperglycemia, may be followed by a reactive hypoglycemia, where the blood sugar is sometimes as low as 59 to 53 mg. per cent (Okada *et al.*, 1929).

Another example of stimulation of the vagal secretory center by substances circulating in the blood may be seen in the effect of amino-acids (Okada, 1930, 1933; La Barre and Destrée, 1935 a, b and c). Okada and his co-workers showed that intravenous injection or intraduodenal administration of large doses of glycocoll, alanin, glutamic acid, histidine or glycylglycine provoke gastric secretion in the dog and in man. After intravenous injection of amino-acids a marked rise of amino-acid nitrogen takes place in the blood, usually coupled with a fall in the blood sugar concentration of varying degree. After intraduodenal administration of glycocoll in man the former phenomenon was observed, whereas the latter did not occur; nevertheless the volume of the gastric secretion increased and its free and total acidities rose.

The secretion provoked by amino-acid could be arrested by administration of atropine or glucose. No gastric secretion could be elicited by means of amino-acid in dogs with the vagus nerves cut in the chest above the diaphragm (Okada *et al.*, 1930) or at the cardia (La Barre and Destrée, 1935 e). Therefore all these facts show that the amino-acids provoke gastric secretion by stimulating the parasympathetic secretory centers in the brain.

La Barre and Destrée (1935 a, b and c), who confirmed the results obtained by Okada *et al.* on dogs, believe that the secretagogue effect of amino-acids is due to the concomitant hypoglycemia. However, it would seem that the amino-acids are able to stimulate gastric secretion directly, although in the experiments in which they were injected intravenously their secretagogue effect undoubtedly was coupled with that of hypoglycemia. This is evident from the fact that the intraduodenal administration of glycocoll in man elicited a flow of gastric juice but did not alter the blood sugar concentration. Moreover La Barre and Destrée (1935 c) themselves observed that the secretion of gastric juice begins before any significant fall in the blood sugar concentration takes place (*e.g.* before the blood sugar level, which had been 92 mg. per cent before the injection, had fallen below 82 or 78 mg. per cent. Further experiments are necessary in order to settle this question finally).

Facts discussed in this section show that during the second or chemical phase of gastric secretion, the vagal secretory center may be stimulated, not reflexly as in the first phase, but directly by appropriate

changes in the composition of the blood. The participation of the parasympathetic secretory innervation also explains why the concentration of pepsin is higher in the gastric secretion of the chemical phase than in that obtained after histamine administration.

CONCLUSIONS

Gastric secretion during its chemical phase is regulated by a triple mechanism: (1) A pyloric hormone, probably "gastrin," acts directly on the gastric glands. (2) Certain food substances, or some products formed or liberated by them, stimulate the gastric glands after being absorbed by the intestine. (3) Some of the absorbed products of digestion, as well as a hypoglycemic state of the blood, act on the vagal centers in the brain.

The effects produced by the stimulants of the chemical phase are manifold: some of them stimulate chiefly the parietal cells, others almost exclusively the peptic cells, and some of them in addition are able to alter the excitability of the gastric glands and so to modify the response of these glands to other stimuli. The fact that there are present in food various secretagogues, which act on different parts of the neuroglandular apparatus of the stomach, is of great importance in the selection of diets for patients with different ailments of the gastro-intestinal tract, as well as for normal persons.

DISCUSSION

DR. HEINRICH NECHELES (Chicago, Ill.): The more we learn about the mechanism of gastric secretion, the more complex it becomes.

So far as we can see from our own investigations, there are two mechanisms which regulate the secretion of the stomach. The one is a stimulating one, and the other an inhibitory one. The stimulating one, I think, we can divide into the neurogenic and the humoral, the humoral being provoked by metabolites, absorption products and possibly hormones. The inhibitory is still very little known, but we think at least two substances must be considered. The one is enterogastrone and the other one is contained in the posterior lobe of the pituitary.

We have recently found that stimulation of the central vagi antagonizes the effects of acetylcholine in the body more or less completely and this may be a true reflex. Since effects of vagus stimulation are more or less due to acetylcholine, there may be a new physiological antagonism in the inhibition of gastric secretion.

The other substance that inhibits gastric secretion is enterogastrone, a substance which has been extracted from the small intestine by Ivy and Lim. We have recently found a similar substance in the urine of normal persons, while the urine of patients with peptic ulcers seemed to contain less of it.

There must be a very fine balance between these stimulating and inhibitory substances which, when disturbed, will be followed by more or less pathological changes in the secretion (and motility) of the stomach.

DR. SAMUEL MORRISON (Baltimore, Md.): There is another secretion in the stomach to which attention should be called. That secretion is the intrinsic factor of Castle. The question has arisen concerning whether this secretion is affected by the pyloric or pyloro-duodenal hormone, and I should like to take this opportunity to ask Dr. Babkin to discuss that phase; for example, the very tissues which have anti-anæmic potency are exactly those which give rise to the pyloric or pyloro-duodenal hormone, and it seems plausible to consider that the mechanism in one case may apply to the other.

It is also said that the pyloro-duodenal tissues as used in the treatment of pernicious anemia act in the nature of replacement therapy, but there is reason to believe, and evidence to substantiate the belief that the action is one of a pyloro-duodenal hormone rather than replacement therapy.

The question always arises as to whether a pyloric hormone exists. Dr. Babkin has pointed out that there is such a specific hormone and that it is probably not histamine. If we take a broader conception of the pyloro-duodenal hormone as we have been led to do from our studies, it is possible to consider it a hormone which stimulates more than one gastric secretion. It has been suggested by certain investigators that histamine is the pyloric hormone. This does not square with the newer evidence at hand as Dr. Babkin and others have shown. Histamine stimulates acid secretion, and perhaps ferments also, but it is an accepted fact that it does not increase the secretion of intrinsic factor. A gastric hormone which has this property must therefore be something other than histamine or something in combination with histamine. In other words, it must be a composite hormone of which histamine may form only one constituent part.

DR. ANDREW C. IVY (Chicago, Ill.): I don't agree with Dr. Necheles when he states that physiological investigations are making the process for the secretion of gastric juice more complex. I insist that these investigations are making this process more simple. We are explaining a mysterious process by discovering several

factors, and when we make such discoveries, or when we take the mystery out of a process, we make the process simple.

Also I do not like the latter part of the discussion of the last speaker, because he states that histamine can't be the gastric hormone simply because it causes the formation of acid alone. He sets up a picture of what he thinks should be the gastric hormone, that it should be something that stimulates both acid and pepsin. I wonder how he can be so sure what kind of hormone the intestinal lining should form to stimulate the gastric gland.

We are not making hormones. We are not making this body work as we think it should work. We are trying to find out how it works.

DR. PHILIP W. BROWN (Rochester, Minn.): We talk about the influence of ingested foods on the gastric secretion, and I have been particularly interested in the factors of foods ingested in relation to nutrition of the body as a whole, and I wonder if there is any relationship at all between the vitamins and these hormones, whether in the B complex or in any of the other mysterious letters of the alphabet. I don't know; I am just asking.

DR. CHARLES W. LUEDERS (Philadelphia, Pa.): "In my studies in 1930-1931 on the effect of Insulin upon external pancreatic secretion, a search through the literature confirmed the finding by himself and numerous investigators: that Insulin stimulates Gastric secretion and Acidity. I would like to ask Dr. Babkin if he has ever studied the effect of the intravenous injection of amino-acids and of fatty acids upon gastric secretion and Acidity, work reported by other investigators; confirming the clinical results following diets rich in these two classes of food elements."

DR. ASHER WINKELSTEIN (New York, N. Y.): I wish to congratulate Dr. Babkin on a further clarification of a very confusing problem, the chemical phase of gastric secretion.

In the presentation we will give this afternoon, we will emphasize the importance of the vagus nerve. It is therefore interesting to hear Prof. Babkin stress the vagus nerve factor in the ulcer problem. At the Mt. Sinai Hospital, the diabetic and gastro-enterological clinics are neighbors. The diabetic clinic has an enormous number of patients. We have several hundred to a thousand

patients with ulcer in the gastro-intestinal clinic. My experience in fifteen years is that the number of patients with diabetes mellitus who have peptic ulcer is extremely small; as a matter of fact, in our experience it is less than the fingers of two hands, over a period of many years, and we have always wondered about that.

It is possible that the hunger mechanism which Dr. Babkin described today may play a role in the symptomatology of ulcer in explaining the hunger pains. It may also play a role in the hypersecretion of ulcer. If it is eventually shown that the hypersecretion of ulcer in some patients depends on a hypoglycemia due to excessive insulinism, that may be the explanation of the antagonism between diabetes mellitus and peptic ulcer. It may even be (although the suggestion is a bit fanciful) that ulcer may prove to be a pancreatic or adrenal disease.

DR. BORIS P. BABKIN (Montreal, Canada, closing the discussion): First of all, speaking about "gastrin," I would like to emphasize that we must be very careful in stating that "gastrin" is a hormone which stimulates the gastric glands during the second phase, because it may be one of those substances, like histamine or choline, which may be extracted from the gastric mucosa and which are also able to stimulate the gastric secretion. Therefore we are not yet entitled to say that the substance extracted by us from the pyloric mucosa and which we called provisionally, "gastrin" is a hormone. There must be some other physiological proofs, which we have not yet obtained, that the extracted substance really plays the part of a hormone. As far as histamine is concerned, I do not think that it is a hormone of the second phase of the gastric secretion. This does not mean that histamine has to be excluded altogether from the picture. I am convinced, for instance, that histamine plays a part during the first or nervous phase of gastric secretion. According to our investigations, histamine stimulates the parietal cells by passing through them, and appears in the gastric juice. I do not think I can answer the question about the Castle's intrinsic factor because I never worked on this problem. A colleague asked me about the effect on gastric secretion of amino-acids and fatty acids. We have the necessary dogs with fistula and pouches and we intend to try on them the effect of these substances. As regards the effect of insulin on gastric ulcer in man, I must admit that I am unable to answer this question.

The Present Status of Treatment in Chronic Gastritis: Gastroscopic Observations

By

WILLIAM A. SWALM, M.D.

and

LESTER M. MORRISON, M.D.

PHILADELPHIA, PENNSYLVANIA

AMERICAN clinicians have been reluctant to accept chronic gastritis as a clinical entity; and during the past few decades the completely accepted conception of gastritis in Europe has here met considerable healthy skepticism. This may be rightly so, for many have found the very wise old adage: "Be not the first to lay aside the old nor the last to accept the new."

Moreover, it should not be forgotten that even one hundred years ago there took place a lively debate between Robert Carswell (1) and Broussais and Louis on the gastritis question. The English Carswell at-

tempted at that time to prove that the pathological demonstrations of Louis and Broussais of the French school, regarding the entity gastritis were erroneous. In sharp contrast is the present recognition of gastritis by the English school, headed by Sir Arthur Hurst and many others. They even believe, as do Faber (2) and Konjetzny (3), that chronic gastritis is a forerunner of gastric carcinoma, pernicious anemia, subacute combined degeneration of the cord and even peptic ulcer (4).

There has also been a similar complete reversal of

opinion by many observers in this country. For example some observers at the Mayo Clinic, like Waltman Walters and Sebenning (5) in 1931, believed that chronic gastritis in the absence of pyloric obstruction did not occur, and stressed the geographical factor of gastritis. They felt that the gastritis seen in Europe was not seen in America. Although Konjetzny, Orator, Puhl and other European investigators have offered pathological case evidence that gastritis is the precursor of gastric carcinoma, Comfort and Butsch (6) at the Mayo's just recently have been the first to our knowledge to demonstrate case records and pathological evidence in which gastritis preceded gastric cancer. A complete change of opinion at the Mayo group is now evidenced by independent reports on gastritis cases by Comfort (7), by Phil Brown (8) and the discussion by Eusterman (9) on Chronic Gastritis in the recent textbook by Eusterman and Balfour "The Stomach and Duodenum." At Johns Hopkins, Gaither and Borland (10) and Freeman (11) have similarly studied gastritis both gastroscopically and pathologically. Even if the gastritis—cancer claim is true in only a minor percentage of cases, proper therapeutic management of gastritis immediately assumes prime significance in the prevention of cancer.

One of the side-effects of the controversy has been that practically all observations have been limited to considerations of the actual existence of gastritis and its diagnosis. One is therefore struck by not being able to find any extensive American observations on the treatment of gastritis, under the direct control of gastroscopic visualization of the stomach and its response to therapy. The few gastroscopic observations on medical therapy of gastritis are mainly the brief ones made by Schindler in his recent textbook (12); the pernicious anemia studies of Jones and Benedict (13); the secondary anemia studies of the French authors Francois Moutier and Paul Chevalier (14); the allergic studies made by Rene Chevallier (15) of Lyons; and isolated case reports. Generally, the European discussors of therapy have focussed largely on the advisability of sub-total gastrectomy; and European physicians and surgeons are still engaged in active controversy on this moot question.

Among related considerations have been the etiology of gastritis and the pathogenesis principally involving gastritis as the possible precursor of peptic ulcer and gastric carcinoma. Numerous contributions have been made recently on the roentgen relief diagnosis of gastritis and one experienced observer—Jacob Buckstein at Bellevue Hospital (16) has gone so far as to claim that the diagnosis of duodenal ulcer can often be materially aided by the roentgen-relief diagnosis of the associated hypertrophic gastritis. Ross Golden has recently similarly described the differential diagnosis of antral gastritis and antral carcinoma and discussed the inherent diagnostic difficulties (17). However, it has been our experience—as in Schindler's that in the majority of cases the roentgen ray diagnosis of gastritis is unreliable since it usually is not corroborated by direct visualization through the gastroscope. It cannot be denied however that the hypertrophic variety of gastritis can often be detected roentgenologically by the mucosal pattern relief, particularly in experienced hands.

Before considering the therapy of gastritis it is important to understand the problem of classification.

All references herein are directed to the chronic form of gastritis and in certain instances the subacute form. No study has been made of the acute form of gastritis which is transient and passing. There is no doubt but that Schindler's classification of gastritis is the simplest and easiest to work with; viz.—atrophic, hypertrophic, superficial and the post-operative forms. However it cannot be forgotten as Chevalier Jackson (18) has pointed out, that it is not comprehensive. After over 35 years of gastroscopic inspection of the stomach Jackson felt that Schindler's classification of gastritis into four groups was not complete and stated that as many as 30 varieties of gastritis require recognition, particularly as significant of the subsequent changes, pathogenesis and development into disease. It was for this reason that we adhered originally (19) to Moutier's classification based on gastroscopic and pathologic structural changes. However to simplify and clarify the issue, we will combine both Schindler's and Moutier's classifications, and attempt simple, concise and yet descriptive terms, such as "atrophic gastritis with erosive features," or "ulcerative gastritis with congestion," or "mixed gastritis" of hypertrophic and atrophic varieties with edema, etc.

Our gastroscopically controlled studies of gastritis therapy embrace from 600-700 gastroscopies. Conclusion as to results were made only if the following criteria were observed in the patients studied for this presentation:

(a) Patients were gastroscoped at least twice (and in some cases as often as eleven times). (b) Patients only were used who had been followed in clinic and private practice regularly and were cooperative. (c) X-ray and biliary studies were negative and extra-gastric pathology was absent. (d) Observations were made in patients followed for a minimum of one year, a maximum of 5 being attained in some. However several exceptions were made in the subacute variety. (e) Patients who had been checked by more than one gastroscopist by the authors and Dr. Chevalier L. Jackson. (f) Routine laboratory studies were made including Wassermans, urines, complete blood counts, gastric analysis, biliary drainage, etc., and various special tests as Gruskin-carcinoma, basal metabolism rate, etc., included.

We therefore enclose the results of our observations according to the English custom as exemplified by Hurst's studies in a small group of cases are carried out. Because of the above criteria a large number of cases was weeded out and a mass statistical report involving several hundred cases was thus avoided. It is felt that better conclusions can thus be reached and hence a small group of each variety is thus presented, each case exemplifying a special point.

We can declare the following opinion at the outset and cite case records in proof:

(1) The atrophic form of gastritis in the absence of primary or secondary anemia has not shown regeneration or return to a normal mucosa in our experience. It has been our custom to grade the atrophies into three grades, from pallor to complete thinning out of the mucosa, effacement of the rugae and blanching. We have not even seen lessening of the pallor in these non-anemic cases. It appears that the mucosa does not regenerate again in these cases under present methods of therapy. We have been interested in the observations of Moutier, Chevallier (20), etc., to the

effect that anemias can be expressed not only in blood changes but also by atrophic gastritis in the absence of blood changes. That is to say, it can be possible for non-anemic anemias to occur just as aleukemic leukemia. They report that their cases of atrophic gastritis anemias without blood changes respond to liver therapy and improve symptomatically. We cannot verify this as yet since we have not had adequate time to check this recent observation. We cannot subscribe to Schindler's belief that atrophic cases should "especially avoid milk, since it invariably causes gas and belching" (21). Not only is this not noticed in pernicious anemia cases where an extensive and severe atrophic gastritis is present but we have not observed this reaction as a general rule in the non-anemia atrophic gastritis. The achlorhydria to histamine that some of these cases present, similarly has not returned to normal despite hydrogen peroxide lavages. This does not corroborate Hurst's and Darling's observations on the return of histamine achlorhydrias in the atrophic gastritis cases under hydrogen peroxide lavages. Our conclusion is rather in agreement with Bockus, Monaghan, et al (22) that improvement but not restoration of acidity occurs. It should be recalled that Hurst's and Darling's and Hartfall's diagnosis of atrophic gastritis were made by gastric analysis and not by direct inspection of the stomach by the gastroscope. Jones and Benedict have shown that pernicious anemia types of atrophic gastritis will have a restoration to a normal appearing gastric mucosa under liver therapy (13).

(2) The congestive, the hemorrhagic or erosive, the ulcerative, the edematous forms of gastritis, whether in subacute or chronic form can and do respond to treatment. These forms are quite frequently associated with the etiologic factors outlined in (1) under therapy, such as upon the removal of offending causative factors these forms will often show a prompt response.

(3) The superficial, catarrhal or mucorrheal form of gastritis responds similarly to therapy but requires that certain implicated mechanical irritant factors be eliminated or ameliorated as in sinus disease especially with purulent discharge (which we see to a great extent in the Philadelphia climate), post-nasal discharge ("drip"), oral sepsis, etc.

(4) The hypertrophic forms per se do not respond to therapy. Symptoms may be absent, yet this form persists and seems particularly susceptible to ease of remissions in symptoms. We have observed only one case in which a transition has occurred from the hypertrophic to the atrophic variety. This is in contrast to the claims by various observers and pathologists (23), with the exception of Schindler.

(5) The post-operative form of gastritis does not respond to therapy although symptoms may be absent.

(6) The mixed types will show improvement on therapy as to congestive, ulcerative, edematous or mucorrheal forms but hypertrophic and non-anemic atrophic features show no therapeutic response throughout and are refractory to all treatment.

We have found in certain instances where the ulcer management with alkalis in forms of gastritis has failed that antacid non-adsorbed substances such as colloidal kaolin in alumina gel or alumina gel alone will prove effective in ameliorating symptoms. This supports Brown and Eusterman's independent observations at the Mayo Clinic. Attempts at medication

adjustment can at the present time be made only empirically. The indications for the use of alkalis or adsorbent demulcent, at present cannot be foreseen as to the type of case in which the one or other should be selected. However, it may be presumed that a more judicious use is made of medication of a more "soothing," demulcent and antacid type inasmuch as we have observed gastroscopically that certain preparations can remain in contact with the gastric mucosa for an hour to two hours.

The so-called pigmented spots seen by the gastroscopists are probably old submucosal or mucosal hemorrhage. We have observed that in those cases where general increase in vitamins is included in the dietary and medication there is a tendency to regression or frequently disappearance. It is impossible to state definitely whether these may have been due to vitamin C deficiency in some cases, as indicative of friability, capillary hemorrhages, etc.

Every gastric post-operative case whose stomach was inspected had definite and often marked evidence of a gastritis. However this does not necessarily imply that these stomachs cause symptoms. They may and they may not. The presence of symptoms in gastritis may depend on involvement not only of an inflamed mucosa but also upon encroachment on submucosal layers where the rich nerve supply is. Thus an inflamed mucosa may indirectly cause pylorospasm or gastric spasm with result in pain or pain-equivalent sensations. It may be that these symptoms are caused by nerve involvement in the gastric submucosa with subsequent pain, distress or equivalents. Or the factor of an inflamed mucosa may be responsible for other types of disturbances—not necessarily painful, but causing gassy distress, anorexia, weakness, symptoms due to disturbances in secretion, etc. Faber, Mays, Moutier and others have shown the frequency of submucosal hemorrhages; edema and infiltrations in these gastritis cases, demonstrating that many of them have more than superficial mucosal involvement. There has been pathological evidence also of the fact that the pathology of certain of the gastritis cases originates in the submucosa. This is analogous to the demonstration by Lewis Gregory Cole (24) who has shown that gastric ulcer may originate as a "boil" like lesion in the submucosa first, with extension up into the mucosa. Moutier has even demonstrated pathologically that the nerve changes are extremely frequent in all forms of gastritis (25).

The sympathetic ganglia as well, he demonstrates, are damaged—involving the plexuses of Auerbach and Meissner. V. Orater, L.d' Amata and P. Mairi have independently shown the same findings pathologically. Confirmatory observations on this nerve affection in gastritis are lacking probably due to the fact that special nerve tissue stains are not used in pathological examinations, as the above investigators have done. These points are raised because of their therapeutic considerations on the claim of some observers regarding underlying autonomic nerve imbalance factors, besides the disturbances in secretion and motility under nerve control.

For example M. Pevsner and O. Gordon (26) have studied 500 cases of gastritis, diagnosed as such by the cytologic study of the sediment as described by Badilkes and by Glaessner. This technique is along similar lines as that reported by Monaghan, Bockus,

Kornblum and Moffat before this Society last year. Pevsner and Gordon emphasized the fundamental factor of neuro-vegetative system imbalance and reported better results when patients were placed on concentrated calcium therapy. This concept of vegetative nerve imbalance may receive some support by virtue of the fact that many of these patients are nervous, irritable, weak, neurasthenic, easily exhausted, or depressed. The question may therefore be asked if it is possible to consider a so-called mucous colitis or unstable colon or peptic ulcer on a neurogenic etiology can it likewise be possible to have a gastritis with neurogenic factors since many of these patients are subjected to as much psychic stress and strain as the peptic ulcer or unstable or so-called "mucous colitis" patients? It is impossible to conclusively answer any of these questions but the clinician handling gastro-intestinal problems cannot help but be impressed by the great psychological factors playing a dominating role in the symptoms of the above conditions and how necessary it is to ameliorate the psychic disturbances in successful therapy.

In the superficial form of gastritis where there is excessive mucus, Schindler and others state that lavage should be carried out every morning over a long time until repeated gastroscopic examinations show the absence of all pathological changes. This has been obviously not feasible as a routine procedure particularly since the superficial forms of gastritis are so common in occurrence. We have met with favorable results in the therapy described below. Schindler states that drugs are not necessary and act as irritants. We have found that alkali preparations, particularly adsorbent ones in the gel forms, are most useful in the removal of mucus, as a local mechanical sedative and in forming a soothing coating over the inflamed or irritable gastric mucosa.

At the present time our present method of therapy in chronic gastritis can be summarized as follows:

(1) Removal of all possible etiologic factors as:

(a) Foci of infection in mouth (oral sepsis), teeth, gums, tonsils, nasal accessory sinuses, etc. (b) Indiction of smoking and alcoholic beverages. (c) Faulty habits of hygiene, inadequate mastication, irregularity of meal-time, food bolting, chronic dietary indiscretions, possibly food allergy, etc. (d) Reflex and contiguous pathology as duodenal disease (ulcer, parasites, etc.), gall-tract disease (infection, inflammation, etc., with continued biliary regurgitation). (e) Correction of autonomic nerve imbalance and psychological abnormalities.

(2) Bland diet, nutritious and emphasizing small frequent feedings.

(a) The atrophic, achlorhydric forms may add seasoning to food, to increase appetite, gastric secretions and weight. (b) The hypertrophic forms involving the ulcerative and erosive varieties should be managed as peptic ulcer cases with bed rest.

(3) Medication varies with degree of acidity, e.g. dilute hydrochloric acid—U.S.P. is given in the atrophic and achlorhydric forms, whereas antacid adsorbents or alkali powders with minimal absorbability are indicated in hyperacidity. Included are vitamins (especially B, B₂, and C (Cevitamic Acid) in all erosive and hemorrhagic types, colloidal kaolin with aluminum hydroxide, antispasmodics (tr. belladonna,

atropine, etc.), iron (ferrous sulphate preferably), sedatives (phenobarbital, bromides), digestants as pepsin, etc.

(4) Gastric lavages, twice and three times weekly in achlorhydric and marked hypochlorhydric types. Excessive mucus, regurgitated bile, retained secretions, etc., are thus removed, avoiding irritant effects and a return to function of the acid-secreting glands may be thus accomplished. Hydrogen peroxide—one-half to one ounce to the pint of warm water is best. The weak silver solutions may be used, but the danger of argyria must be borne in mind.

(5) Spa waters, as Vichy, Kalak, Carlsbad, Saratoga Springs, etc., for their lavaging effect and mineral content.

(6) Physical therapy—local heat by baking, moist applications, diathermy, all for pain (High voltage X-ray for intractable hypertrophic forms still in experimental stages).

(7) Surgery to be used only in very severe and intractable cases with severe ulcerative and chronic hemorrhagic features. Post-operative inflammatory reactions locally, however, must be expected.

(8) Prophylaxis—the possible development into peptic ulcer, gastric carcinoma, or pernicious anemia in some forms, indicates that the principle of periodic health examinations should specifically be applied in these cases. Hence gastroscopic examinations and X-ray studies should be repeated at stated intervals, depending on the financial circumstances of the patients. Preventative medicine here is all-important.

In the large series of gastritis cases which we have treated during the past four years, it becomes apparent that although these therapeutic measures may frequently give very satisfactory results, these measures are entirely inadequate in the non-anemic and the hypertrophic forms, and in certain of the erosive as well. Here is a significant and important field of investigation and also of preventive medicine if it is possible that the hypertrophic and atrophic forms are among the precursors of gastric carcinoma, ulcer, pernicious anemia, etc., as so many observers believe and as growing evidence would appear to suggest.

The following groups rather than a large statistical series are presented in order to bring out facts concerning the forms of gastritis including their pathogenesis, response to therapy, course, and instructive features.

ILLUSTRATIVE CASE ABSTRACTS SUPERFICIAL, CATARRHAL OR MUCORRHEAL GROUP:

Case 1. E. C.; male; 42; locomotive engineer.

(1) Clinical Picture: (a) epigastric burning pain 1 to 1½ hours P.C. of 4 years intermittent duration, increased by food and alkalis (soda, etc.); (b) chronic sinusitis; (c) tender in epigastrium to palpation.

(2) Gastroscopies: 1/29/36 — Considerable mucus throughout stomach of gray tenacious and frothy varieties with slight congestion. Impression: Mucorrheal (superficial) Gastritis.

3/4/37 — Only scanty mucus present of frothy type, no congestion or other abnormalities.

(3) Treatment: Weekly nose and throat treatments for posterior ethmoidal sinusitis from 1/31/36 to 3/2/37. Adjuvant therapy, bland diet, antispasmodics, sedatives.

(4) Course: 3/2/37—Complete disappearance of symptoms for first time in four years—remaining asymptomatic until the present.

Case 2. H. B.; male; 54; unemployed.

(1) Clinical Picture: (a) anorexia, nervousness, constipation, upper abdominal "soreness"; physically, epigastrium tender to deep palpation.

(2) Gastrosopies: 3/1/35—Increased mucus in patches throughout stomach, grayish and whitish, tenacious in nature. Impression: Marked catarrhal gastritis.

1/13/37—Several atrophic segmented areas; one erosion of hemorrhagic nature; mucus +2.

2/24/38—Unchanged from last examination except no erosions, but rugal crests are reddened in congestive aspects. Impression: Atrophic Gastritis with former erosive and present congestive features.

(3) Treatment: Bland diet, emphasizing small, frequent feedings, alkali powders one hour P.C., sedatives, kaolin in alumina gel one hour A.C., antispasmodics.

(4) Course: Symptoms continue unaltered.

Case 3. A. T.; male; 24; tailor.

(1) Clinical Picture: (a) "indigestion" 3 years constant duration, (epigastric distress immediately P.C. with belching); (b) bloating sensation; (c) nervousness; (d) weakness; (e) physical examination negative.

(2) Gastrosopies: 1/17/37—Moderate superficial gastritis, with thick mucus patches and slight edematous features.

1/21/38—slight decrease only in mucus.

4/22/38—Considerably less mucus (+1); no edema; considerably improved.

(3) Treatment: 1/17/37 to 1/21/38—Bland diet, with small frequent feedings; colloidal kaolin in alumina gel, agar-agar, vitamin concentrates (Wheat germ), alkali powders P.C.; belladonna A.C.: 2% hydrogen peroxide lavages twice weekly for months.

(4) Course: Unaltered from 1/17/37 to 1/21/38. On the institution of hydrogen peroxide lavages, after two months, gained 6 lbs. (4/22/38), stronger, slight "indigestion," less nervous, feels much better.

DISCUSSION

These three cases are selected rather than a large series because each brings out the salient features concerning this form of chronic gastritis. Case No. 1 demonstrates the fact that many of these mucorreal, catarrhal or superficial gastritis patients will show satisfactory response when mechanical or focal infective agents are treated successfully. In this instance the treatment of diseased sinuses with purulent discharge into the stomach was considered responsible for the patient's "cure." Case No. 2 demonstrates the fact that certain of these superficial or mucorreal cases are going through an evolutionary development, this patient developing into the atrophic type and proving refractory to our accepted forms of treatment. This is the type described as the "Alternative" form by the French authors, having changed from one type to the end form, the atrophic variety. The significance of these changes remains unknown, but it is possible that continued observation will shed light on this subject. Particularly important is the fact that despite rigorous medical treatment his symptoms continue unabated. It should be recalled here that a great many gastric cancers have gastric symptoms for many years before the development of their carcinoma. Case No. 3 illustrates the fact that patients cannot be always treated by rote. He failed to respond to the usual methods of therapy for one year, including bland diet, with small frequent feedings, alkalis, sedatives, antispasmodics, commercial kaolin and other preparations, vitamins, etc. etc. However, upon the institution of a two months' course of hydrogen peroxide lavages, the patient promptly responded satisfactorily both as to the gastrosopy and clinical pictures. Hydrogen peroxide lavages (2%) have a place in our therapeutic armamentarium in selected cases. Whether they can restore a histamine achlorhydria to normal acidity remains a very dubious question.

ULCERATIVE, EROSION OR EDEMATOUS FORMS:

Case 4. J. W.; male; 23; counterman.

(1) Clinical Picture: (a) epigastric boring pain shortly P.C., relieved by food or alkalis of several months duration; (b) melena (twice); (c) anemia; (d) physical examination reveals oral sepsis (carious teeth, pyorrhea).

(2) Gastrosopies: 3/3/36—Numerous erosions and oozing with evidence of recent submucosal hemorrhages. Along the greater curvature just underneath the esophageal entrance a large U shaped ulceration which oozed freshly. A deep linear excavation lateral to this area. Impression: Erosive, ulcerative gastritis.

3/16/37—A few superficial pigmented spots present only. No ulcerations seen.

(3) X-ray—Gastro-intestinal series negative for pathology.

(4) Treatment: Strict, modified ulcer diet; alkali powders; antispasmodics; sedatives; high vitamin; dental care.

(5) Course: Completely asymptomatic from 3/10/36 on to date of last gastrosopy 3/16/37.

Case 5. C. W.; female; 49.

(1) Clinical Picture: (a) severe intermittent gripping pains in the epigastrium, P.C., relieved by food or soda—of 2 years intermittent duration; considerable nervousness; physical examination negative.

(2) Gastrosopies: 4/5/35—Several small circular erosions on the anterior wall, lesser curvature of the body. Fresh oozing from some. Impression: Erosive gastritis.

4/15/36—No erosions, only several dark brown pigmented spots.

(3) Treatment: Ulcer management, with modified Sippy, antispasmodics; alkalis; rest; sedatives; vitamins.

(4) Course: Gaining weight, occasional gassy distress on minor dietary indiscretion; greatly improved.

Case 6. W. M.; male; 53; machinist.

(1) Clinical Picture: (a) dull gassy distress with pain in epigastrium and left lower chest (over the heart) of 10 years duration; (b) dyspnea, palpitation and vertigo; (c) loss of 12 lbs. weight in past year; (d) physical examination negative.

(2) Gastrosopies: 1/14/38—Moderate edema, considerable tenacious mucus; several moderately large, dark erosions, also pigmented patches along lesser curvature pars media. Impression: Edematous, erosive and mucorreal gastritis.

2/1/38—Slight edema, slight tenacious mucus. No erosions, occasional pigmented spot.

3/4/38—Slight edema and mucus. No erosion or pigmentation.

4/5/38—Stomach almost within normal limits except for a very slight edema in the area of the incisura angularis.

(3) Treatment: Bed rest, ulcer diet (at first Sippy, later Modified); alkali powders; sedatives and antispasmodics.

(4) Course: On 2/1/38 after bed-rest, patient is considerably improved and all symptoms markedly alleviated. On 3/4/38 patient has gained 14 lbs., is completely asymptomatic and states that he "never felt better in his life." On 4/5/38 patient continuing to gain and felt in perfect health.

DISCUSSION

Case No. 4 demonstrates (a) that not infrequently gastric ulceration is picked up when expert roentgen-ray studies are negative. This is particularly true when the ulceration is not deep or is in the more proximal parts of the stomach; (b) Oral sepsis when marked, as in this patient, can be instrumental in production of a sub-acute ulcerative, erosive gastritis which can show prompt therapeutic response when the cause is removed and intensive treatment instituted. This patient was of the sub-acute variety, judging from the short duration of symptoms, the marked gastric changes and prompt response to treat-

ment. (c) When these cases continue for any length of time without rigorous treatment, it is probable that they go on to a severe refractory form as in Case No. 13 or as those cases where the European surgeons perform subtotal gastrectomy. Schindler has used the Coutard X-ray therapy in intractable cases, but because of the tremendous radiation involved we have not attempted this method. Case No. 5 shows that since mild symptoms and some pigmented spots were still present at the end of one year, that some permanent changes in the stomach had occurred, that therapy should be continued, and that a relapse could be experienced quite readily in all probability. Continued observation is therefore particularly indicated in this type of case. The question of Vitamin C deficiency in these erosive types is an important one since these patients frequently relate unbalanced dietaries, poor in vitamin content. This has particular reference to those clinic patients on the "welfare relief." Case No. 6 is especially interesting because of the symptoms referable to the cardio-vascular system, such as pre-cordial pain, palpitation, dyspnea, and vertigo. These were apparently due to gassy distention in the gastro-intestinal tract with reflex disturbances in the heart, as we have been able to demonstrate experimentally in the human subject. If these disturbances and reflex manifestations are permitted to continue over for prolonged periods, they can most certainly produce heart damage or cause sudden, dangerous and even fatal cardiac abnormalities, as we have shown. Other interesting features are the fact that the etiology in this case is unknown and yet the therapeutic response was remarkably prompt. One would have thought that because of the 10 year intermittent duration of symptoms an advanced and difficult gastritis would be present, and yet this proved not to be the case.

ATROPHIC GASTRITIS WITH HEMORRHAGIC, OR "MIXED" FEATURES:

Case 7. V. M.; male; 22; hosiery worker.

(1) Clinical Picture: (a) constant epigastric discomfort and pain about $\frac{1}{2}$ hour P.C. unrelieved by food or alkalies—1 year duration; (b) headaches (sinus disease) and post-nasal discharge; (c) nervousness; (d) weakness; (e) physical examination reveals tenderness particularly in the epigastrium, but distributed over the upper abdomen as well.

(2) Gastrosopies: 1/27/37 — Markedly segmented atrophic areas in the fundus, which were small in size. Diffuse arborization of the submucosal vessels in the fundus, also along the greater and lesser curvature, which were glazed. Rugae throughout definitely effaced. 3-4 smooth, punctate, reddish spots of a hemorrhagic nature in the fundus, with oozing; mucus +1 tenacious. Impression: Atrophic gastritis with erosive features.

2, 10/37 — Less oozing and hemorrhagic spots; slight congestion in fundus. Atrophic areas unaltered, mucus same.

3/1/38 — No hemorrhagic or oozing features. Atrophy still same. This tenacious mucus still present, but definitely lessened.

(3) X-ray findings: G. I. series negative. Marked sinus disease (antral and frontal). Gastric analysis: normal acidity.

(4) Treatment: Antacid powders, sedatives, antispasmodics; bland diet; vitamins; tonics;—finally submucous resection and nose and throat treatments.

(5) Course: Above medical therapy gave only slight improvement with symptoms unchanging until submucous resection and nose and throat treatments given intensively. Then for the first time definite improvement in the symptoms and gastroscopic picture noted.

Case 8. W. M.; male; 25; stone-mason helper.

(1) Clinical Picture: (a) frequent gassy distention and distress in the upper abdomen; (b) weakness and nervousness; (c) physical examination negative; (d) gastric analysis — normal acidity.

(2) Gastrosopies: 4/11/35—Mucosa quite atrophic in segmented areas, with arborization of many bluish vessels. Very glistening aspect of fundus. Impression: Atrophic gastritis Grade 2.

12/2/36 — Grayish mucosa, atrophic, patchy, venous arborization. One pigmented spot in fundus.

12/16/37 — Pale segmented atrophic areas in fundus and lesser curvature, anterior portion. Effacement of folds here. On posterior portion mid-fundus, oozing area from friable mucosa. Impression: Atrophic gastritis with friable mucosa.

(3) Treatment: Bland diet, small frequent feedings; rest; antispasmodics; sedatives; high vitamins; colloidal kaolin in alumina gel.

(4) Course: Moderate improvement; less nervous; less weak and gassy, but mild symptoms still present and exacerbated on working hard, mental strain, or dietary indiscretions.

Case 9. L. C.; male; 40; laborer.

(1) Clinical Picture: (a) intermittent epigastric pain and distress unrelated to meals; (b) pyrosis; (c) weakness; (d) physical examination negative; (e) acidity subnormal.

(2) Gastrosopies: 9/2/36 — Mixed congestive, atrophic (segmented areas with arborization) and mucorrheal (+2) gastritis.

10/23/36 — Moderate improvement, less congestion, less mucus.

3/11/38 — Still atrophic features, no congestion, slight mucus.

(3) Treatment: Bland "smooth" diet; alkali powders; antispasmodics; sedatives; vitamin concentrates.

(4) Course: Marked improvement, only slight symptoms present occasionally.

Case 10. S. G.; male; 55; machinist.

(1) Clinical Picture: (a) epigastric pressure distress several hours P.C.; (b) loss of 20 lbs. and weakness; (c) occasional tarry stools; (d) physical examination—epigastric tenderness; (e) hypochromic anemia (hgb. 60%); (f) histamine achlorhydria.

(2) Gastrosopies: 10/9/35—Moderate pallor in patchy areas—fundus and pars media with venous arborizations and moderate rugal effacement and friability. Impression: Atrophic Gastritis—Grade 2.

6/10/36—Color definitely less pale with less conspicuous arborizations, still friable.

1/13/37 — Friability to slight extent, but color within normal limits.

(3) Treatment: Feosol, dilute hydrochloric acid; hydrogen peroxide lavages; smooth bland diet; sedatives.

(4) Course: 1/13/37 — Blood count returned to normal limits; gaining weight; only occasional distress.

DISCUSSION

Case No. 7 demonstrates the importance of focal infective and mechanical irritant factors as with this marked sinus disease accompanied by heavy, purulent discharge. This is in all probability the advanced stage of Case No. 1, where a mucorrheal gastritis of sinusitis etiology occurred. However in case No. 7 the superficial or catarrhal form had probably progressed to the atrophic variety as in Case No. 2. This patient responded only slightly to medical therapy, but when submucous resection with amelioration of the sinusitis took place, a definite improvement in the gastroscopic and clinical picture occurred. Case No. 8 shows that certain of the atrophic varieties really are never free of symptoms, although with constant care, the patient may temporarily be free of symptoms. These cases are frequently those with easily upset, "delicate" or sensitive stomach where slight dietary indiscretions or strain, etc., will bring on symptoms. Case No. 9 illustrates that numerous cases with "mixed" features of atrophic, congestive and mucorrheal varieties in different areas in the same stomach, can improve

symptomatically when the associated congestion and mucorrhea respond to therapy and disappear from the gastroscopic picture. Case No. 10 demonstrates the fact that whereas the non-anemic types of atrophic gastritis remain unaltered under therapy, the forms accompanied by secondary or primary anemia will return to a normal gastroscopic picture under specific therapy with liver, or iron as in this case. The melena suggests hemorrhages from gastric erosions. Cases No. 7 and 8 show that normal acidities occur in the atrophic forms of gastritis, where the atrophic aspects are not diffuse. However, when a histamine achlorhydria occurs as in case No. 10, despite return to normal appearance, the achlorhydria remains, in our experience.

HYPERTROPHIC, MIXED FORMS:

Case 11. E. F.; male; 42; unemployed.

(1) Clinical Picture: (a) epigastric burning and hunger pains 2-3 hours P.C. intermittently for several years, relieved by food or alkalis; (b) considerable mid-epigastric pain to palpation; (c) normal acidity.

(2) Gastroscopies: 12/17/36—Moderate hypertrophic features fundus, anterior and posterior aspects. Antrum considerably congested and contracted. Moderate mucus throughout. Impression: Hypertrophic gastritis with congestive and mucoid features.

3/15/38—Antrum normal in color, no contractures. Hypertrophic fundal features still present. Slight to moderate mucus.

(3) Treatment: Strict ulcer regime with modified Sippy, rest in bed; alkali powders; sedatives; antispasmodics; vitamin concentrates.

(4) Course: Marked improvement clinically, only slight and occasional symptoms.

Case 12. M. T.; female; housewife.

(1) Clinical Picture: (a) mid epigastric discomfort and dull pains in the upper abdomen with nausea, of 2 years duration intermittently; (b) constant gassy distress and belching; (c) nervousness, sensation of lump in throat; (d) burning sensation in tongue; (e) physical examination—tenderness upper abdomen to palpation; (f) normal acidity.

(2) Gastroscopies: 5/9/35—Erosions in small area, excessive mucus, hypertrophic rugae. Impression: Hypertrophic gastritis, with erosive and catarrhal features.

4/3/38—Moderate pallor, effacement of rugae, arborization of veins in submucosa, oozing erosion. Impression: Atrophic gastritis Grade 2 with erosive features.

(3) Treatment: Smooth bland diet; alkali powders; carminatives; charcoal; colloidal kaolin in alumina gel; sedatives; vitamins; rest and bromides.

(4) Course: Continued exacerbations and remissions in symptoms every two months, upon any slight dietary indiscretion, emotional upset, or upper respiratory infection. Last gastroscopy done during exacerbation.

Case 13. I. C.; male; 23; movie manager.

(1) Clinical Picture: (a) sharp epigastric pain with burning sensation 30-60 minutes P.C. relieved by milk, cream or alkalis—5 months intermittent duration; (b) melena on two occasions accompanied by severe abdominal pain and vertigo; (c) marked nervousness; (d) physical examination—exquisite tenderness over epigastrium; (e) Grade 2 hyperacidity; (f) X-ray studies negative except for "spastic colon and adhesions."

(2) Gastroscopies: 4/30/37—Antrum spastic, contracted, hypertrophic, edematous with thickened angularis folds. Very marked granular aspect on lesser curvature. Impression: Mixed hypertrophic gastritis with edematous and spastic features.

4/5/38—Considerable spasticity throughout, angularis contracted and twisted, increased mucus, hypertrophic appearance and edema still present and mammelonated aspect on posterior wall, lesser curvature.

(3) Treatment: Following laparotomy 5/1/37 for suspected peptic ulcer, which was not found, strict ulcer

regime instituted, including 3 weeks bed-rest; alkali powders; continuous alumina gel drip; colloidal kaolin; sedatives; antispasmodics; modified Sippy; all ineffective, symptoms unaltered.

(4) Course: Following 8 months intensive therapy, sub-total gastrectomy performed. Upon greater lapse of time, clinical evaluation will be made.

DISCUSSION

Case No. 11 demonstrates the fact, observed in other cases, that hypertrophic mixed varieties can mimic the ulcer syndrome, particularly if the antrum is involved in the process. The marked improvement in symptoms was accompanied by the disappearance of the associated congested, inflammatory appearance of the mucosa, and lessening in mucus. However, exacerbations in these patients, where the gastric mucosa is persistently abnormal, are promptly produced by indiscretions, upper respiratory tract infections, stress and strain, etc. Case No. 12 shows that the hypertrophic form can develop into the atrophic form, despite our present therapy. Associated erosive features may persist. This patient appeared to have symptoms in cycles of 2-3 months, with remissions of equal periods. Exacerbations were usually precipitated by dietary indiscretions. This case as well as others in the hypertrophic variety point out the inadequacy of our therapeutic approach which is due to our ignorance of the actual processes which are operative in these transitions. If Hurst is correct in believing that the patients with hyperacid and anacid stomachs inherit this constitutional diathesis, it may be that hereditary factors in the hypertrophic and atrophic form of gastritis are similarly responsible. Case No. 13 points out (a) the fact that the "mixed" hypertrophic, edematous forms can simulate ulcer, when this is proven absent by roentgen studies and internal as well as external inspection and palpation of the stomach and duodenum during laparotomy; (b) that melena may be associated; (c) that despite the most intensive medical management and treatment as of ulcer, with 3 weeks bed-rest, etc. etc., a certain number of these cases have to be resected via sub-total gastrectomy, just as the medically intractable ulcer case. This is analogous to those severe gastritis cases where the European surgeons perform sub-total gastrectomy as a routine, often without preliminary medical trial. This recalls similarly some surgeons who did posterior-gastro-entrectomy or ulcer excision some decades ago for ulcer without recourse to preliminary medical trial.

POST-OPERATIVE GASTRITIS:

Case 14. S. P.; male; 65; former peddler.

(1) Clinical Picture: (a) sub-total gastrectomy for Gastric Carcinoma, proven pathologically, on 8/24/31, with a history mimicking gall stone colic of two years previous duration, no extension or metastasis; (b) within three months post-operatively had gained 13 lbs. in weight, felt stronger but from then up to 4/19/35 has had vague but considerable epigastric gassy distress and belching; (c) anorexia; (d) blood studies throughout have been entirely normal up to the present time; (e) histamine achlorhydria present throughout; (f) vague upper abdominal tenderness to palpation.

(2) Gastroscopies: 4/19/35—Marked congestion throughout, particularly on the rugal crests. Increased mucus. Projecting knob of tissue seen on the lesser curvature, probably the result of a cicatricial contraction following gastrectomy.

5/24/35—Appearance unaltered.

10/30/35—Appearance unaltered.

2/21/36—Appearance unaltered.

4/19/38—mucosa still reddened and congested. The rounded knob of tissue previously described still unchanged, on the lesser curvature. Friability of the mucosa with slight oozing on the posterior wall. Large amount of

thick tenacious mucus. Impression: Post-operative gastritis with congestive, friable, and mucorrhea features.

(3) Treatment: For the first four post-operative years dilute hydrochloric acid, small frequent feedings; rest; tonics; enzyme mixtures. No medication or dietary past 3½ years.

(4) Course: For the first four years, post-operatively, vague considerable epigastric gassy distress and belching, with rare upper right quadrant colicky pain, radiating to the right shoulder. During the past 3½ years the patient was practically symptom-free and abandoned medication and diet, "eating everything." Weight constant but at times feels weak.

Case 15. T. B.; male; 36; brakeman.

(1) Clinical Picture: (a) mid-epigastric hunger pain 1½ to 2 hours P.C., immediately relieved by food or alkalis, intermittently for 3 years duration—one year previous to emergency pyloroplasty for ruptured pyloric ulcer and 2 years after despite ulcer regime; (b) one year after pyloroplasty, cholecystectomy done for gall stones, and search made for peptic ulcer on operating table, none found in stomach or duodenum; symptoms still persist; (c) physical examination—considerable tenderness over the epigastric area; (d) gastric analysis—Grade 1 hyperacidity.

(2) Gastrosopies: 1/21/36—Marked hypertrophy of the rugae noted in the lower fundus. Moderate congestion and increased mucus throughout. Intensive spasm and contracture of the angularis. Impression: Hypertrophic gastritis with congestive and spastic features.

12/23/36—Less congestion and mucus; decreased spasm, hypertrophic features constant and marked.

2/22/38—Hypertrophic and other features unchanged.

(3) Treatment: Strict ulcer regime, Modified Sippy; alkali powders; colloidal kaolin in alumina gel; pure alumina gel; antispasmodics; sedatives.

(4) Course: After pyloroplasty, slight relief on ulcer regime; but symptoms moderate and persistent throughout, and unaltered by removal of gall stones. Referred for roentgen-irradiation.

DISCUSSION

Case No. 15 as well as some others in our unpublished series demonstrate that a hypertrophic form of gastritis can continue to produce the ulcer type of pain. This is in keeping with the Scandinavian school under the aegis and stimulation of Knud Faber. For example Andersen (27), Dahl, Holsti, Nicholysen and others have operated upon cases diagnosed as chronic ulcer, only to find gastritis and duodenitis which in their experience could produce duodenal deformity or spasm. This patient similarly demonstrates the fact that the gastric post-operative case is left with a gastritis which may or may not be symptomatic, and which does not appear to respond to treatment. The disturbance in the circulation and nerve supply created by surgery on the stomach may be the contributing factors. This patient has experienced slight relief following both operations, but his hunger pains 1 to 2 hours after meals still persist despite the intensive therapy. Several other intractable patients including this one with the hypertrophic variety are now being treated by deep roentgen therapy, using 15 weekly treatments of 50 Roentgens each. However it is too early to judge results as yet. Case No. 14 is of great interest because of the duration of recovery, being asymptomatic 7½ years after removal of a large carcinomatous mass saddling the lesser curvature, the malignancy measuring 10 x 4 cms. Symptoms were of two years duration pre-operatively. It is also noteworthy that in the absence of any therapy, the blood picture is entirely normal and the patient asymptomatic, despite the age (65 years). Just as in other cases it is noted that the inflammatory reaction may be temporarily asymptomatic, so peptic ulcer in some individuals may be unaccompanied by symptoms and not even suspected until ushered in by a sudden hemorrhage. Of a similar nature are the peptic

ulcer cases with brain tumor, as Cushing has shown, in which no gastro-intestinal symptoms are present. In the same category are the observations of certain pathologists as Robertson (28) at the Mayos, who found in 1926 that as much as 12% of routine autopsied cases, when carefully studied show evidence of old peptic ulcer scar, etc. Although some of these patients have had gastric complaints, many have not.

SUMMARY

1. Our present methods in the treatment of chronic gastritis are outlined and discussed.

2. Present therapy objectively, and sometimes subjectively, in the hypertrophic and non-anemic forms is inadequate, due chiefly to insufficient knowledge of pathological processes.

3. The congestive, edematous, catarrhal, ulcerative and erosive forms of gastritis are usually most responsive to medical therapy as viewed objectively and subjectively; i.e. by gastroscopic observation and clinical evaluation of the patient.

4. New therapeutic approaches in chronic gastritis should be investigated, particularly with reference to (a) hypertrophic, verrucose or mammelonated forms and (b) non-anemic atrophic forms.

5. The gastritis problem should be studied jointly and interdependently by the pathologist and gastroscopist clinician for the purpose of achieving a better understanding of the nature of gastric changes in health and disease. Such studies may also reveal the pathogenesis of gastric ulcer and carcinoma.

DISCUSSION

DR. EDWARD B. BENEDICT (Boston, Mass.): Mr. President and Members of the Society: I have enjoyed Dr. Swalm's paper very much. I should like to comment on the classification first. It seems to me that until we have performed more gastroscopies, we should still adhere to Dr. Schindler's classification very strictly, as he has had so much more experience than anyone else in this country.

When we speak of congestive, hemorrhagic, erosive, ulcerative, or edematous gastritis, I think we are only confusing the picture. We can speak of superficial gastritis with edematous features, congestive or hemorrhagic features, and we can speak of hypertrophic gastritis with these features, and atrophic gastritis with these features, but it is important, I feel, and quite possible clinically to stick strictly to Schindler's classification so that in the literature there will be no confusion.

When Dr. Swalm states that hypertrophic forms do not respond to therapy, that they are refractory to all treatment, I think he must be referring solely to the gastroscopic picture, because certainly clinically many of these patients are cured for long periods of time.

With regard to the treatment of gastritis in general, I think Dr. Swalm has covered almost all the features, but I should like to emphasize particularly the importance of the teeth in gastritis; as a matter of fact, I think that dentistry should be more closely connected with gastroenterology and medicine in general than it is at the present time, and I think, particularly in gastritis, the teeth are of paramount importance.

I also feel that alcohol, tobacco, general hygiene, and diet are important. Dilute hydrochloric acid has been found very effective in the atrophic types with anacidity, and in some of the hypertrophic types with anacidity. The administration of alkalis is also important.

With regard to gastric lavage, most of our patients have responded without the necessity of lavage, and we have not had occasion to have much experience with that method.

Bed rest has also been largely unnecessary in most of our cases except in the very acute and hemorrhagic varieties where I think bed rest is important.

With regard to surgery, I think that should be almost wholly confined to the cases which have had hemorrhage. Thank you!

DR. ERNEST H. GAITHER (Baltimore, Md.): I do believe that gastritis is a proven disease entity. It is my wish not to be known as a reactionary or a pessimist, and my desire at all times is to align myself with the progressives; however, I do consider that the diagnosis of intragastric lesions is not quite so simple a problem as one might be led to believe after reading some of the reports presented during the past few years.

As to the diagnosis of gastritis, it is, in my opinion, not so easy and simple as it might seem, and what one observer would consider truly indicative of this condition would not be so diagnosed by another equally skillful observer.

The mucous membranes of the body in the conjunctiva, nose, mouth, throat, rectum and bowel, differ greatly in

every individual, as do the facial features and conformity of bodies; however, just because there is a difference, one is not justified in arriving at the conclusion that disease is present.

We must remember that while the present instrument is one of splendid accomplishment, yet it has by no means been perfected and we cannot obtain a very satisfactory picture of the proximal (silent) area. Again, it is certainly no easy task to visualize and adequately describe a duodenal ulcer, and it is in this area that the majority of peptic ulcers occur; furthermore, it is most difficult to differentiate between benign ulcers and those undergoing early malignant changes.

Certain it is that in the majority of gastrojejunal ulcerations, the lesion cannot be visualized.

Much progress has been made in this most valuable diagnostic adjunct; however, much more is to be accomplished, and we shall note continued progress; however, my plea is that we continue our intensive studies, encouraging the technicians to further efforts looking toward an improved instrument, and advising all clinicians to continue their intensive studies in the presence of a sane and judicial attitude, well remembering the limitations of the method, and not allowing our enthusiasm for its value to outweigh our good judgment.

DR. RUDOLF SCHINDLER (Chicago, Ill.): I enjoyed Dr. Swalm's and Dr. Morrison's paper very much and I am very happy that they have confirmed many of my previous opinions, especially about the difficulty of curing hypertrophic gastritis. I think if one tries to evaluate a therapy for a disease of such a long duration, as chronic gastritis is, one can come to definite opinions only after a very long period of observation.

It is necessary at first, and perhaps this could be answered to Dr. Gaither, to have a very good knowledge of the normal gastric mucosa. If one has an opportunity, which is so difficult in this country, to get a knowledge of the mucous membrane of the stomach of many entirely healthy people, one will find there is such a thing as a definite picture of a chronic gastritis, and then only it becomes possible to follow the course of such a disease as chronic gastritis through long years. Naturally, it is not very good to combine too many different kinds of therapy, because one will not know which was successful and which was not.

There are many cases of superficial gastritis and also of atrophic gastritis, which improve definitely without any therapy, and it is extremely difficult to say that a certain therapy was valuable. I had the opportunity, however, to follow one case of ulcerative gastritis over a period of ten years without seeing any improvement of the clinical condition or the gastroscopic picture. When this patient was treated with high voltage X-ray therapy after Coutard, all the symptoms and manifestations disappeared completely. In this one case we can say that therapy was effective. And after similar observations I would like to emphasize that I think superficial chronic gastritis is less prone to develop into the atrophic or dangerous form when frequent lavage is used, and I think this is valuable therapy. Silver therapy is less recommendable because some patients show increased irritability and increased pain.

I have seen one case of atrophic gastritis without pernicious anemia which responded to liver therapy confirming the observation made by P. Chevallier.

I entirely agree with Dr. Benedict in the points he brought up.

DR. CHESTER M. JONES (Boston, Mass.): I think it is obvious from Dr. Swalm's paper, which brings up many interesting points, and from the discussion to date, that the Association is due for a good many papers on gastroscopy for many years to come. We may be about to run the gamut on gastroscopy that we have already run in the discussion of peptic ulcer.

After reading Dr. Swalm's paper, and after reading Dr. Schindler's book on gastroscopy, I feel certain that we still do not know all of the variations of the normal stomach. I am sure there are going to be a large number of cases, without symptoms, labeled gastritis because of what was seen on gastroscopy. I think one cannot lay too much emphasis on the necessity for knowing all the variations that may occur and still be within normal limits. For example, what are the variations in the appearance of the normal stomach in the different decades? I am sure that one will get different gastroscopic pictures at different periods during life, and one could easily make the mistake of saying "This is gastritis," when, as a matter of fact, the changes were merely those normally incident to the fifth or sixth decade.

There is one point mentioned by Dr. Swalm which I think warrants a little comment. He has referred to the gastric changes noted in pernicious anemia as being those of atrophic gastritis. My own impression, from following some of these cases with Dr. Benedict, is that the term atrophic gastritis is a misnomer when applied to pernicious anemia, and I think this may possibly be true of other deficiency conditions. Dr. Swalm also referred to the non-anemia anemias, an expression which, I think, indicates that in his mind, as well as in mine, there is a real doubt as to what the situation implies. I am sure that there are degenerative gastric changes caused by deficiency conditions which mimic atrophic gastritis closely and which are very hard to distinguish from pernicious anemia. These changes are entirely comparable to the atrophy noted in the tongue and the rectal mucous membrane, and yet under proper liver therapy there is a striking return toward a normal appearance. A similar condition, I think, undoubtedly holds in pellagra, and Dr. Ruffin and Dr. Borland have both told me of recent observations they have made of pellagra patients. Their observations would seem to bear out this suggestion—that the atrophy in deficiency conditions is not that of gastritis. It is important that all such variables be thoroughly studied and understood as they occur in normal individuals and in patients suffering from nutritional disorders.

DR. WALTER L. PALMER (Chicago, Ill.): Mr. Chairman, the other discussants have said about all that I wanted to say, but I will reinforce their remarks by a few more or less categorical statements.

I do not wish to be considered a heretic or a reactionary any more than Dr. Gaither does, but the situation calls for a few frank statements. I am convinced that anatomically there is such a thing as gastritis. I am quite convinced that there are symptoms resulting from hypertrophic gastritis and postoperative gastritis. I am not at all convinced that there are any symptoms from atrophic gastritis or superficial gastritis.

We know nothing about the etiology of any type of gastritis. We know very little about the course of gastritis. Our experience has certainly shown that gastric changes may occur rapidly in the gastric mucosa. One gastroscopic examination may show a normal appearance, another, a superficial gastritis, another, an atrophic gastritis, and another, a hypertrophic gastritis. If such changes can occur in a few months' time, what does it all mean?

I question very much the wisdom of studying the effect of treatment on gastritis until we know more about the nature of the condition or disease, whichever it may be, its cause, and its natural history.

The list of the various possible causes supports this point of view: foci of infection, alcohol, faulty hygiene, reflex disturbances, contiguous pathology, regurgitation, autonomic nerve imbalance, etc. The multiplicity of treatments likewise illustrates our lack of definite knowledge: hydrochloric acid, vitamins, drugs of all kinds, gastric lavage, and so forth. I suspect that the same therapeutic results could have been obtained by psychotherapy, pure and simple.

DR. DAVID H. ROSENBERG (Chicago, Ill.): I have had the privilege of treating two cases of combined superficial and atrophic gastritis and one case of hypertrophic gastritis, diagnoses of which were made by Dr. Schindler from gastroscopic examinations, by means of parenteral liver extract, and in none of these cases have we noted any improvement gastroscopically. One case of atrophic gastritis, in fact, showed a progression of the mucosal lesion. In the case of hypertrophic gastritis we did not anticipate any improvement by such therapy.

It would seem that what Dr. Jones has suggested may be true; that when we are dealing with true gastritis, liver therapy may not produce the same dramatic results which he, as well as others, have observed in the treatment of so-called atrophic gastritis associated with pernicious anemia, and that the latter form of gastritis may be really a deficiency disease or its manifestation.

DR. ELMER B. FREEMAN (Baltimore, Md.): I would like to say a few words in reference to the classification of chronic gastritis and the gastroscopic appearance of the gastric mucosa in pernicious anemia. With our present knowledge of chronic gastritis, I feel very strongly that we should adhere to a very simple and concise classification. For clinical purposes, I know of none better at the present time than the one Dr. Schindler has given us and which also has been stressed by Dr. Benedict.

From gastroscopic studies, I do not believe that the changes in the gastric mucosa which occur in pernicious anemia are the same as those which occur in chronic atrophic gastritis. Certainly, the gastroscopic appearance is entirely different.

DR. WILLIAM A. SWALM (Philadelphia, Pa., closing the discussion): We are merely presenting the results of our observations for the past four or five years and I am very glad that we did so because it has brought out some very interesting discussions.

So far as classification is concerned, of course, Dr. Schindler surpasses us all in experience. We are associated with an artist, Dr. Jackson, one who believed that at least thirty different varieties of gastritis could be seen, even before Schindler's 'scope was invented. This caused us to hesitate to accept the classification into four varieties as we should think it should be. We really still believe that the classification will change in spite of all that has been said today.

We also agree that many of these cases do not need lavage. We did not lavage one-half of our cases.

Dr. Schindler says he thinks there are too many therapies. We gave you a compilation of all the therapies we could possibly get together, and we have tried them all out. After all, in America, the patient wants results and doesn't desire to be a guinea pig. Therefore, we employed total management.

Dr. Jones believes also the statement regarding the variables in symptoms. Symptomatically chronic gastritis is a difficult thing to diagnose and, of course, our observations are based on the gastroscopic findings, together with a careful examination and routine studies. Everyone who went through our clinic had "the works," just as Dr. Lyon does it, and you know how thorough he is.

I had always believed the same as Dr. Jones does, that pernicious anemia was not a gastritis with pernicious anemia, until I saw the slides of Knud Faber, where he showed the abnormal histologic changes and revealed that it is an inflammatory condition. Personally I did not think so either at that time, and it is interesting that Dr. Jones picks up the same former trend of thinking. It may be that these pernicious anemia cases of Knud Faber's were complicated cases and may have had pernicious anemia with secondary gastritis and not primary gastritis with pernicious anemia.

I am always interested in hearing Dr. Palmer, especially since he is linked with Dr. Schindler, and when he says that he is still somewhat doubtful about the nature, cause,

and so forth of gastritis, it almost makes one feel as though one should sit down. He has watched Dr. Sehindler, who instructed me, and still believes that the nature, cause, etc., are not established.

As I said, our work is a compilation of all authors, and

we attempted to treat our patients in a total management way, the same as most of you do. If you do not help your patient one way, you will often swing to another, even if you do have to resort to psychotherapy, which we think is an important factor as well, just as Dr. Palmer does.

Psychiatric Contributions to the Study of the Gastro-Intestinal System

By

EARL DANFORD BOND, M.D.
PHILADELPHIA, PENNSYLVANIA

IN limiting myself in this paper, I have kept in mind three fields—the gastro-intestinal system, its connections with the rest of the patient through the endocrine and autonomic nervous systems, and the mental field, connected with the other two. I shall discuss this last field.

The psychiatrist finds opportunities to study the gastro-intestinal tract first in his psychotic patients. A few cases will illustrate the ways in which digestive symptoms are built into the psychoses, and used by patients.

A woman of 48, referred for involuntional melancholia, had never in childhood been without a digestive disturbance; she had always been sickly and pampered. Her conscience was always uncomfortable and drove her to become a missionary; all arrangements were completed when she was prevented from carrying them out by typhoid fever, of all diseases. After this she went back to her preoccupation with nausea and vomiting—her chief life occupation.

In cases of early dementia praecox in three boys aged 16, 18 and 20, descriptions are available of digestive events of early childhood. In all appeared neurotic oversolicitous parents. Vomiting, refusal of food, colitis began in infancy and continued as methods to dominate the family. One boy gets out of school by nine o'clock vomiting; another, "when his sick stomach does not allow him to work, spends his time fishing, gunning, or fox-hunting." In all three boys, delusions now cluster about these preferred gastro-intestinal reactions.

A story of feeding difficulties was obtained and verified in a girl of 13 with dementia praecox. The mother's main object in life was, and still is, to feed this child. But the child bit and scratched during early breast feeding; she refused milk from a bottle. Description of feeding difficulties are taken from hospital records when the child was two years of age. She grew up on a limited diet: she broke any milk bottle she could find; she refused to come to family meals—she ate by herself irregularly—she bit and scratched other children, and for this reason she was dismissed from school. At a hospital school she gained in ability to get on with people but she became emaciated, when she was not forced to eat. Her mother preferred the other side of the dilemma and placed her in a mental hospital where she was tube fed, gained thirty pounds, and became katatonic. She could not be well nourished and well behaved at the same time.

If we turn now to patients whom the psychiatrist would call "neurotic," we find many of them referred

by internist and pediatrician. And in these cases the use of the digestive symptom as a symbol stands out clearly.

A woman says: "I struggle between a feeling of being dirty and a reluctance to brush my teeth or go near a dentist. As an infant I nearly starved because I would not take milk. Now I am babyish—I can't talk."

A college girl as a baby had been coaxed to eat. At 8, when her curls were cut off, she had a severe diarrhea. In college she had to read cookbooks all day; she had to supervise the preparation of her own meals: she became emaciated.

Psychiatric contributions to the diagnosis and treatment of disturbed functions of the digestive tract center about four considerations. It is taken for granted that investigation of organic factors has first been made without yielding a full explanation of the condition and a clear line of therapy. After this search, what suggestions can be made to the general physician, the gastro-enterologist and the pediatrician?

(1) Fundamental is the need to manage infant feeding according to Aldrich's method for preventing anorexia (1) and Gesell's suggestions (2). Aldrich outlined a plan which included marked reduction in diet at the first sign of anorexia, avoidance of sudden changes in food and of close supervision by parents and pitched battles at meal times. Equal interest in the training of sphincters should be shown by the attending physician. Both of these constructive preventive measures are aimed at keeping the parents from showing anxiety disproportionate to the situation. If this infant training could be well done, symptoms as they come to the gastro-enterologist and psychiatrist would be greatly modified for the better.

(2) With conditioned autonomic reflexes in command of many gastro-intestinal disturbances, efforts can be made in reconditioning. When colitis or vomiting are results of known emotional stimuli, a complete change in the emotional state of the family may break the chain. For example, if vomiting is welcomed and expected instead of dreaded, it may stop. In colitis, if the stimulus is brought on with the bowel empty, it may lose its effect.

If early signs of emotional excitement appear, Cannon suggests that it is best not to eat until the emotional reverberations have died down.

(3) Psychological conflict, a rather vague term to the physician, was partly brought to book when the physiologist discovered the autonomic nervous system.

A child at dinner with a big appetite and a big sense

of guilt (or fear of a stern parent) has a conflict between the antagonistic cranial and mid-autonomic divisions for the control of the stomach.

Going further, some conflicts are so disagreeable, so shameful, that they are put out of consciousness. A craving is met by refusal to recognize it, which means a continued stirring up of the appropriate autonomic path. "Repressed affect," says Kempf, "seems to be stored (like a coiled spring) in the heightened postural tension of the autonomic apparatus."

One roentgenologist suggests watching the colon under the X-ray when searching for an emotional conflict. He says that the expression of the colon is more honest than that of the face.

Apparently there are emotional repressed factors even in ulcerative colitis. Sullivan and Chandler (3) report that symptoms of ulcer followed directly upon specific emotional disturbances. A personality study of the adult patients showed that all were immature. In these cases psychotherapy was used with good results.

(4) The foregoing considerations may have prepared you for the last step—into psychoanalysis. More specifically I want to give you suggestions derived chiefly from Freudian investigations. I find it hard to evaluate them.

No one would deny, I think, that any strong emotion has a general bodily resonance and will express itself in that organ which is the weakest link, which has been in some way conditioned, sensitized. Nor can there be much doubt as to certain organs being symbols—in common life, in child life, in the vulgate. The mouth symbolizes taking in, incorporating, loving—more than once I have heard delirious patients talking of devouring their mothers. The stomach symbolizes disgust, for one thing. Cardiospasm can come when an annoyance, an insult, has to be swallowed. Leaving out of consideration the small intestine, it has been harder for me to be sure of the symbolization of the colon. Certainly for children, and for many childish adults, the operation of the colon—rectum—sphincter is the most important event of a day. The psychoanalyst says this organ symbolizes giving; in infancy something given to the world to get a mother's praise.

After this introduction let me quote exactly the results of studies of colitis in the Chicago Institute for Psycho-analysis. "In all of these patients we find an increased inner urge to give to others, to make restitution, and to compensate for aggressive acquisitive wishes. This urge to give expresses itself in the form of increased elimination of intestinal content instead of giving of real values. This increased elimination also expressed an aggressive attack on others. It is a substitution both for a gift and for a hostile aggression." By the analysis of 5 patients with colitis, 4 have been freed of their symptoms without any special diet.

In the Chicago series another group included gastric neuroses and duodenal ulcers. In these patients was found the demanding attitude which was met either by an internal shame and guilt or was thwarted by external circumstances. "As the demand for love, service, and protection since early infancy is closely associated with the wish to be fed, the unsatisfied demanding conditions serve as a permanent stimulus of the stomach. They mobilize the wish to be fed which

becomes independent of the periodic organic hunger and leads to permanent irritation of the stomach—"chronic neurosis or ulcer."

Last week I heard about an ulcer patient from Dr. Draper, with his anthropological slant. Stomach pains began when his wife suddenly told him that she was pregnant. "His world dropped out from under him." Ulcer developed, and Dr. Draper says it was maintained by a milk diet. At the time of a later pregnancy the ulcer bled. The man had had several emotional upsets: he resented his wife's fondling the baby instead of himself: he felt that a "rival had taken his wife away": he felt like "killing the baby."

There are some guides to personality study which emerge from all these considerations.

In every functional and most organic cases psychiatrists would urge consideration of the patient's personality under these headings.

(1) Early eating habits and early attitudes toward family, school work, life. (2) Present day emotional stresses and strains, frustrations, happiness or unhappiness, especially in marriage. (3) Does the patient make his gastro-intestinal organs the symbol of anything?

Such study should be given at least one uninterrupted hour. It often happens that a patient will fill the first half hour with organic complaints, coming in the second half hour to emotional attitudes. Such patients say that they never have had a chance to tell their whole story until they came to a psychiatrist. This full hour is important, although I can agree with Dr. Crothers that in the stress of practice it is immensely difficult for an hour to be given without neglect of other duties. The listening doctor can take in statements in any order but should then arrange them chronologically. The patient's personality should emerge as an integrated system of habitual adjustments to the environment—especially to other people and to food.

There should then be no attempts to classify the patient. Description is better and safer. Psychiatrists are beginning to distrust most classifications of personality as inadequate. There are definite psychotic and neurotic patients. But they are small in number as compared to the great numbers of people who are simply unhappy, tense, frustrated or resentful. In all sorts and conditions of men there is need to watch for emotional conflicts displaced to the digestive tract.

With a description of personality tied up with the other symptoms, the whole situation of the patient, that is, the complete diagnosis, will be ready for use in treatment.

In closing, a sentence is appropriate from a paper given to this Society in 1932 by Dr. Adolf Meyer: "Often the gastro-intestinal tract with its receptive, digestive and eliminative functions can become that which expresses and leads the personality . . . throughout life."

DISCUSSION

DR. FRANKLIN W. WHITE (Boston, Mass.): I am not a psychologist, and I am not sure that I am qualified to discuss a paper of this kind, but Dr. Bond has shown us how digestive symptoms are built into the psychoses, and I am sure in listening to him we realize that he sees

a certain group of patients who are perhaps more likely to go to the psychologist than to the man interested in digestive diseases.

He stressed the importance of psychiatric study. Every history is in some way a personality study. If a patient sits down and tells us his troubles, by the time he has talked for a half hour we have sized him up; we know something about his day, his habits, his hobbies, his joys and sorrows; he has given us more than a picture of his digestive symptoms; he has given us a picture of himself.

Of course, this takes time and, as Dr. Bond has said, when the patient comes to a stomach specialist, he tells about his stomach first, and only after a half hour or so does he begin to unburden himself of some of these secret and other troubles which are so important.

I think perhaps the commonest things, which we will simply mention, are the direct effects of emotion on the digestive tract, so well known to us all, the nervous vomiting, nervous diarrheas, and so forth.

Then Dr. Bond has spoken of something more deep-seated and elusive, these concealed or unconscious effects, which he has explained by the Freudian conception of a symbolism in the gastro-intestinal tract, that these various digestive symptoms are outward signs of repressed mental conflicts.

This whole situation brings us into real, practical mistakes and difficulties, without doubt. It is a very common mistake to exaggerate the discovery of some minor physical ill or something which turns up on physical examination. We find a local tenderness, or a little too much or too little acid, or a doubtful Graham test, or some malposition of the pelvic organs, and may overlook the powerful psychic factor which is the real cause of the symptoms.

Recently, I saw a patient who told me of her eighteen operations; it seemed as if everything in the abdominal cavity had been taken out or tinkered with, and only after about an hour's talk did I discover the major factor, a perfectly unbearable home life; while all these operations had helped very little or even made her worse, she responded at once when she was taken out of her home surroundings and given proper psychotherapy.

Another difficulty may sometimes appear in seeing psychotic patients in sanatoria. A middle-aged woman loses her appetite, and loses weight, and has local pain, and the question arises, is she developing a cancer in the abdomen? These symptoms require careful study but often enough in such cases are merely a manifestation of psychotic troubles.

I have made the simple observation a number of times in the psychoses, that the patient who comes in at the time of an active wave of depression has a lot of gastro-intestinal symptoms, and when that cyclic psychotic depression disappears, then the patient is entirely symptom free so far as the digestive organs are concerned, until another wave of depression appears.

As to ulcerative colitis, it perhaps has occurred to many of us to wonder whether the colitis eases which Dr. Bond was speaking of had simply an irritable colon or whether they really were patients with deep-seated organic change.

I should like just to say a word about some recent work done by Dr. Lium, a surgical resident at the Boston City Hospital, with reference to the etiology of ulcerative colitis. He has made colonic explants in a number of animals and watched them, and finds that when we have stimulating factors which cause spasm and irritation, the injection of some toxins, drugs which act on the parasympathetic system, etc.—we have first, spasm of the explant, followed, often enough, by irritation and ulceration. Since emotion surely causes spasm, there is a possibility that some of these cases of colitis may develop in this way.

With regard to treatment, I have one question. Of course, we all try to allay the fears of these patients, to

banish the thought of cancer or serious disease of any kind, and try to encourage them, and carry out proper hygiene, with rest, or gentle exercise, and the use of sedative drugs in a judicious way, and try to teach them some simple philosophy of life which will lessen their anger and excitement and rush and grief. I should like to ask Dr. Bond whether he feels it is within the scope of the ordinary internist to go a step further and try to unearth some of these unconscious emotional conflicts, which seem to be so very important, and to try to get rid of them.

I think we all ought to be grateful to Dr. Bond for discussing the psychic source of so many gastro-intestinal symptoms.

DR. ALBERT J. SULLIVAN (New Haven, Conn.): Dr. Bond has given us some exceedingly valuable material and he very kindly and gently hinted that it is up to us to put it into practice.

For some years I have been spending from one-half hour to an hour and a half on the study of personality factors in every patient who has come to me, irrespective of the diagnosis, that is, whether the condition seemed to be an organic disease or purely a functional one, and last week I reviewed two hundred cases on which I had the follow-up of at least eighteen months, and attempted to group them according to the importance of emotional factors.

That has been done numerous times in the past but usually with an "either or" classification, that is, the patient either had organic disease or had a functional complaint.

I found very shortly that my cases could fall definitely into four groups. The first class was a group of patients who had no organic disease of the gastro-intestinal tract, and the symptoms were entirely emotional, not organic. In this group was a large number of anxiety states, a few actual psychoses, a few which could best be described as Dr. Alvarez terms it, as "insanity equivalents." This group makes up 18 per cent of the total number of patients. In my estimation the treatment of this group is entirely psychiatric. Much of it can be done by the internist or the gastro-enterologist. Some of these patients may improve temporarily on a series of injections or hospitalization, or a therapy which removes them from their environment, if they go to some sanatorium or clinic, but they will promptly relapse and their symptoms recur, when they get back into the environment which is causing the difficulty.

The second group of patients consists of patients who have no organic disease. The symptoms are due to a combination of emotional factors and poor habits and malfunction. For example, there is the irritable colon and the mucous colitis patient. There is no doubt at all that habits of eating, enema habits, cathartic habits, play a large role in those cases, and there is no doubt in my mind that emotional factors play a large role. The treatment is a combination of psychotherapy, if that is what you wish to call it, and dietotherapy, and change in the patient's habits of irritating the colon by cathartics or enemas. That group makes up 25 per cent of the total group.

The third group is a group which most of you would probably feel is an artificial group, but it is a group which I feel very definitely about. It is a group of patients with definite organic disease but, in my opinion, in these cases emotion plays a very large role in the etiology, particularly in the onset of recurrences, and I speak chiefly of two organic diseases, most peptic ulcer cases, and most cases of ulcerative colitis. That group makes up 27 per cent of the total.

The fourth group is a group in which organic disease plays the whole role and emotional factors have little or no significance, and that group is made of such things as carcinoma, cholelithiasis, cirrhosis of the liver, and things of that sort. This group is 31 per cent of the group.

DR. RUDOLF SCHINDLER (Chicago, Ill.): In 1927, von Bergmann, of Berlin, published an important paper on the tearing down of the organ neuroses.* He contended that in many cases in which formerly we would have diagnosed them as neurosis, improved methods of examination, such as cholecystography, biliary drainage, gastroscopy, have taught us the presence of severe anatomic changes.

This certainly is true, but we should not forget the great role which psychic influence plays in organic disease, as Dr. Bond stated, so that in almost every instance of chronic disease, except operable carcinoma, the question arises whether systematic psychotherapy would not be preferable to somatic treatment. On this point I entirely agree with Dr. Palmer, although I believe that superficial and atrophic gastritis have very definite symptoms. Moreover, evidently genuine organ psychoneuroses exist and they develop especially in the alimentary tract, for reasons well known to the psychiatrist, and described by Dr. Bond, especially the symbolism of the organs, which is so obvious and cannot be overlooked.

What we need is a definite prognosis and indication for the special therapy in each case. Not every patient should be analyzed. Take for instance, the frequent, though usually not diagnosed, proctostasis, that form of obstipation in which the rectum has lost its sensitivity, the ampulla being filled with feces without the patient's feeling it. In my experience only a very few cases have simple causes such as bad habits at the act of defecation and respective conditioned reflexes. Most of them are genuine psychoneuroses. These again may be subdivided in two categories. One of them concerns young unmarried girls. The disturbance lies very superficially only, and can be treated by simple persuasion and simplest forms of suggestion. This type of therapy is useless in the second form. If patients of the second type are analyzed, severe infantile regression is found. These cases need thorough psychoanalysis. The "depth" of this psychoneurosis is great.

Most cases of cardiospasm are cases of genuine organ psychoneurosis, and surgeons, as Sauerbruch, have described how easily it may be cured by simple hypnosis. Its depth is not great. Such cure, however, is possible only in about the first half-year after the start of the disease. Later the reflex is conditioned, and psychotherapy becomes useless.

The reason for psychogenic diarrheas may lie extremely superficially, so much as not to need any therapy. In other cases these diarrheas are so deeply rooted in the personality of the bearer that extensive analysis is indispensable. What we need, therefore, is: to come to *correct indications* for psychotherapy by the use of all methods of examination and by the determination of the "depth" of the neurosis, and to suggest the *proper kind of psychotherapy*, which depends on this "depth," on the duration of the disease, on the age of the patient, and on other factors, such as surroundings, intelligence, and so forth.

DR. JOHN L. KANTOR (New York, N. Y.): I should like to say a few words from the point of view of the practising physician. It seems to me we would like aid from the psychotherapist, and we need it, but the cards are so stacked against him that I am not sure much can be accomplished. Unhappily, there seems to be a great deal of fatalism about this type of patient. In the first place, he is presumably endowed with an unstable psyche by virtue of inheritance; and, secondly, he seems to be tremendously buffeted about by the strain of life. In neither of these instances is there any possible chance for the physician to change the situation.

As to therapy, so far as the symbolism is concerned, that is all very interesting but it doesn't help one very much. What the patient needs is someone in whom he has enough confidence—whether he will do it at the end of one hour or the end of one year—to tell his story and what

ails him. Direct pressure from the outside may fail in this. It is something that must come from the inside, a spontaneous deliverance. I am not at all sure that it is always physicians that are going to cure many of these patients. They need restoration of confidence, peace, and some faith, perhaps religious faith, that we as doctors are not necessarily the ones to give.

DR. WALTER C. ALVAREZ (Rochester, Minn.): I should like to say a word of appreciation of Dr. Bond's paper and of the officers for their good sense in having a talk like this on the program. We ought to have one or more every year, because there is no question that we do not always recognize insanity in our patients. For instance, recently a physician sent me a patient with a letter stating that the woman had an amebic diarrhea which wouldn't clear up with treatment. He apparently had not noticed that the real trouble with the woman was that she was in a spell of melancholia. He had been hunting, as most of us do, for a physical disease in the abdomen to explain a disease of the brain. The woman has since attempted suicide, and when I last heard of her she was where she belongs, in a hospital for the mentally unbalanced.

Every year I see patients who have been operated on time and again for a supposed intestinal obstruction which is not found; why? Because it is in the woman's mind. As I grow older in the practice of medicine I hope to develop more skill in differentiating two types of nervous patients: one, the type that I can help because they are primarily sensible, tractable, teachable and cooperative people who are tired, hypersensitive, nervous and upset because of a long period of overwork or strain or unhappiness. These people will make an effort to get well, and with rest and sedatives and a proper understanding of their trouble, they will usually pull out. I am happy to give these people all the time they need because such time is usually well spent, and in many cases I am later rewarded by learning that the patient is well. The other type of patient we can often recognize from the start. Sullen and uncooperative, or too stupid or undisciplined or psychopathic to cooperate with the physician for more than a few hours at a time in an attempt to reform bad habits, or obsessed by fears or crazy ideas, or too queer to mix with their fellows, what can one hope to do for them? Usually we waste what time we spend trying to help them.

I have little use for psychoanalysis, because so often one begins with a congenitally psychopathic person and ends up with one. To show what I mean, let us take the case of William Ellery Leonard, who can't go 50 feet from his house because of an agoraphobia. He tells in his book "The Locomotive God" that he was psychoanalyzed by several experts and that they dug out the cause of the trouble, a fright when he was four years old. They brought this fear out in the open, and according to Freud he should be well, but he isn't. He still can't go out.

DR. EARL D. BOND (Philadelphia, Pa., closing the discussion): I appreciate very much the sympathetic reception which this paper has had. You might have objected to many parts of it.

I was interested in Dr. White's statement that these psychological patients came to the psychiatrist first. I had understood that of psychotic patients, a certain few were in mental hospitals and the rest were about consulting gastro-enterologists and internists as to why their gastro-intestinal symptoms made them feel as they did.

On the other hand, Dr. White's question as to what should be done by the gastro-enterologist, was answered beautifully by Dr. Schindler, and I should like to associate myself with everything that he said. I take it that emotional factors often turn out to be very practical ways of handling some gastro-enterological disturbances. It is often the internist who gets a chance to deal with the emotional factor just, so to speak, as it is hovering over

*v. Bergmann: G. Zum Abband "Organneurosen" als Folge Interner Diagnostik. *Deutsch. Med. Wo.*, 53:49, 1927.

the gastro-intestinal system and ready to settle into it. Now, the way the physician who is dealing with the gastro-intestinal upset handles that critical situation may determine the onset or the prevention of a long neurosis.

The psychiatrist is likely to get to most of these things second and third hand, and so is handicapped.

In the matter of symbols and what they mean, the psychiatrist would ask this of internists: Isn't there something in your own study of the personality as you come to it without prejudice that will help in the understanding of symbolization, and of the importance of the emotional element in gastric and intestinal disturbances?

Studies on the Use of Aluminum Hydroxide Gel in the Treatment of Peptic Ulcer

By

EDWARD S. EMERY, Jr., M.D.

and

ROBERT B. RUTHERFORD, M.D.

CLINICAL experience teaches that one can divide patients with gastric and duodenal ulcer into 3 groups, depending upon the severity of the disease: the mild, moderate and severe. The mild and moderate cases do well with any good medical or surgical regime. The severe cases present a serious therapeutic problem because they respond unsatisfactorily to both medical and surgical treatment.

Of the severe cases, patients with hypersecretion present the greatest problem in therapy. Not only does the stomach secrete a large amount of highly acid juice during the day, but the empty stomach is prone to secrete large quantities of acid at night. Because it has been shown by Mann and Williamson (1), Matthews (2) and others (3) that the free hydrochloric acid is an important factor in the development and chronicity of an ulcer, it is obvious that strict neutralization of the gastric juice will give the best opportunity for healing to occur. Although Sippy designed his regimen to produce complete neutralization, the treatment may not accomplish this objective in the patient with a hypersecretion, for the following reasons:

1. The tendency of the stomach to respond to alkali by an increased secretion of acid reaches its peak in the presence of a marked hypersecretion.

2. Secretion continues during the night in many instances and prevents healing.

3. The onset of alkalosis as a result of the large amount of alkali which may be required.

Therapeutic efforts are defeated frequently by failure to obtain complete neutralization of the gastric juice before the patient is in alkalosis, and by the return of an uncontrolled secretion after the alkalosis has disappeared. The surgical results in this group of patients are unfortunate. Jejunal ulcers and other undesirable effects are prone to follow all types of operative procedures.

In 1929, Crohn (4) stated that colloidal aluminum hydroxide is an effective antacid, that it reduces total acidity to a point where complete cessation of subjective symptoms is almost an invariable rule and that it is non-absorbable and non-toxic. He found that it produced prompt relief from pain and heartburn in cases of functional hyperacidity and gave almost immediate relief from peptic ulcer distress in twenty

patients whom he had studied. Others have confirmed these statements. Einsel and Rowland (5) report that after three weeks of treatment the hyperacidity of peptic ulcer is reduced to normal or subnormal levels. Also, it has been stated (6) that the secretion of acid does not return to former levels for several weeks after the discontinuance of the aluminum hydroxide. A preparation which can neutralize the gastric contents and decrease the production of acid should be useful in controlling hypersecretion.

However, the literature provides little information on the type of ulcer case which has been treated. One would like to know whether aluminum hydroxide can control those patients who respond unsatisfactorily to our usual therapeutic measures.

The object of this paper is to present some observations on the action of colloidal aluminum hydroxide in the severe type of case.

PRESENTATION OF DATA

To date, we have started treatment with colloidal aluminum hydroxide on 21 patients. Fourteen were admitted to the wards of the Peter Bent Brigham Hospital, to whom the medication was administered by the constant drip method, as described by Woldman and Rowland (7), for one week and then orally in hourly doses. Seven patients were started only by the oral method in the Out-Patient Department and were ambulatory from the beginning. All these patients had proved resistant to past treatment. Twelve patients represented the most severe type of case for one or more reasons. Nine fell into the group of the moderately severe. Eleven of the severe cases had a marked hypersecretion, in 8 of whom the gastric contents were never controlled satisfactorily by one or more treatments on the hospital wards with the Sippy regime. Four had never been hospitalized for economic or social reasons and had not responded to an ambulatory treatment. Four of the most severe type had suffered a previous perforation. One of these had had a gastric ulcer and later a duodenal ulcer perforate. Five had had previous surgery, two of whom were left with a jejunal ulcer and the other three continued to have severe pain. The situation of one of the severe cases was complicated also by nephrolithiasis.

Seven were classified as moderately severe because

Chart 1. The average free and total acidities in the gastric contents of 12 patients before and during treatment with colloidal aluminum hydroxide.

they continued to be bothered by symptoms although following a good ambulatory treatment.

We were able to obtain satisfactory data on only 12 patients, five of whom were treated by the drip method and seven by the oral method. Several patients refused to continue the treatment because they objected to the tube, or to the taste of the material. A number of others would not come in for gastric analyses although they were satisfied with the results and continued with the treatment. Eight of the twelve patients on whom we have data were in the "severe" group and four in the "moderately severe" group.

The routine has been as follows: A gastric analysis was performed on all patients before the onset of treatment. The analyses were repeated at weekly intervals on nearly all cases. The aluminum hydroxide was omitted for 24 hours before the analysis to avoid any immediate effect. The same method was used each time; that is, a Levine tube was passed either nasally or orally and the fasting contents removed. Fifty cc. of an 8 per cent alcoholic solution was then injected into the stomach and 10 cc. specimens taken at intervals of 20, 40, 60, 90 and 120 minutes. An injection of $\frac{1}{2}$ cc. of histamine hydrochloride, 1-1000 solution (the equivalent of $\frac{1}{2}$ mg) was then injected and the gastric contents allowed to syphon off for one hour. All titrations for free and total acidity were done in the usual way with Topffer's solution and Phenolphthalein as indicators. Those patients who started on the drip method were shifted to the oral method after one week. The preparation known as Creamalin has been used through the courtesy originally of the Cleveland Chemical Associates and later of the Albap Pharmaceutical Co., Inc.

A solution of one part of the aluminum hydroxide (Creamalin) to 3 parts of water was used at all times. The amount which was used varied slightly, but on the average 15 drops per minute were allowed to drip through the tube. It was given orally in amounts of 60 cubic centimeters of the mixture per dose. A dose was given every hour from 8 a.m. to 9 p.m.

In addition to the aluminum hydroxide, the patients were fed according to the schedule outlined by Sippy. They received 90 cc. of equal parts of milk and cream every hour and feedings were gradually introduced until 6 small meals were being taken at the end of the first week. The 6 small feedings were changed to 3 moderate-sized meals after 3 weeks.

All patients were relieved of their ulcer distress within 24 hours and had no recurrence of pain while remaining on the treatment. Several patients stated that their stomach felt "easier" under the aluminum therapy than with the alkaline powders. The only complaint of those who have followed the treatment has been severe constipation in some instances. Nearly all the patients have had to take some mineral oil and some have been troubled in spite of large doses of oil. Our studies show that the colloidal aluminum hydroxide is a satisfactory antacid if given in large enough doses. Tests were made for the presence of free acid at numerous times throughout the day and at varying intervals during the course of treatment. No free acid was found at any time during the day while the aluminum was being administered.

In addition to its neutralizing the secreted acid, we have confirmed the fact that it decreases the titratable acidity of the gastric juice. Chart 1 shows the effect on the titratable acidity of all patients over a period of 12 weeks, by recording the highest readings obtained with the alcohol meal. The free acidity dropped from an average of 68 before treatment to approximately 35 after treatment. The total acidity has followed closely the free acidity in all instances. Its drop is rapid on the drip therapy and reaches its low point by the end of the first week. Our experience shows that a week is required for the acid to reach its lowest level and that a continuation of the drip beyond this time does not cause any further decrease in the titratable acidity. Oral administration of the drug produces a somewhat slower decrease in the titratable acidity which ultimately reaches the same general level.

Chart 2. The average free and total acidities and the average volume of the fasting contents of 12 patients before and during treatment with colloidal aluminum hydroxide.

Chart 3. The average free and total acidities and the average volume of the fasting contents in five patients to whom aluminum hydroxide was administered through a Levin for one week and afterwards by mouth.

The effect on the fasting gastric contents is shown in Charts 2, 3 and 4. There was little change in the volume of juice. However, the treatment resulted in a definite drop in the free acidity approaching an achlorhydric condition in many instances. Studies on the fasting contents also demonstrated that the free acidity drops more slowly in response to the oral therapy than if the patient is started on the drip method. It required about 3 weeks for the free acidity to reach the same level in the oral cases as occurred in the drip cases, at the end of the first week.

The free and total acidity decreased in response to stimulation by histamine. However, histamine resulted in a greater volume of juice after treatment with colloidal aluminum hydroxide. The volume averaged 98 cubic centimeters before treatment was instigated and gradually climbed to 120 cubic centimeters at the end of 10 weeks. (Chart 5).

DISCUSSION OF DATA

It is evident that colloidal aluminum hydroxide is an effective drug for controlling gastric acidity. It has been possible to neutralize and to maintain complete neutralization in every case. Furthermore, it decreases the acidity per unit volume of gastric juice. This has been found in all the specimens studied whether fasting, after alcohol, or after histamine. However, the results with histamine suggest that the treatment may not affect materially the amount of acid secreted. Because of the greater volume, the total amount of acid which was secreted by these patients after histamine was only slightly less than before aluminum hydroxide was given. (see Chart 6). We have no data which will explain the increased volume. The total solids in the gastric juice are apparently the same before and after treatment. The figures for our cases are as follows: Total solids before treatment and after alcohol were 0.544 grams per cent. After one and a half months of treatment they were 0.572 grams per cent following alcohol and 0.535 grams per cent after histamine. Likewise, the amount of protein

in the juice was similar before and after treatment. We have no data on the total base, but Adams, Einsel and Meyers (6) state that the values are closely correlated by an inverse relationship to the figures for free and total acid concentration. This may explain why there is an increased volume with a decreased amount of acid per unit volume.

We were interested particularly in discovering how treatment with aluminum hydroxide affects the condition known as hypersecretion. Of the 11 patients with this condition, 7 were relieved of all symptoms within 24 hours upon administering the aluminum by the drip method. Six of these patients had failed to obtain complete relief with the Sippy regimen. In addition to the aluminum producing prompt relief, it decreased effectively the free acidity in the fasting contents, as determined at the time of the gastric analysis. The same effect was found upon samples obtained from the stomach at midnight. The free acidity which averaged 39 units before treatment dropped to an average of 11 units after treatment. In two patients the free acidity averaged 5 units five months after treatment was begun. However, the volume of the night aspirations did not change. The average volume before treatment was 98 cubic centimeters and later was 106 cubic centimeters.

Four patients with a hypersecretion were treated in the Out-Patient Department. All of them were more comfortable than before the aluminum was started. One of them was enabled to continue actively his work as a dynamiter although he was unable to work at the time he consulted us.

The evidence which has been cited makes us believe that colloidal aluminum hydroxide is indicated in the treatment of the patient with a hypersecretion, a night secretion, or both. It is advisable to administer the aluminum hydroxide by the drip method at the start. This ensures complete neutralization of the gastric juice at all times throughout the 24 hours. In this way, the ulcer is freed almost immediately from the harmful effects of the hydrochloric acid. The rapid

Chart 4. The average free and total acidities and the average volume of the fasting contents in seven patients to whom aluminum hydroxide was administered by mouth from the beginning.

Chart 5. The average free and total acidities and the average volume of the gastric contents in response to 0.5 milligram of histamine. These figures were obtained from the total amount of juice which siphoned off the stomach in one hour.

relief from pain at night permits complete rest and ensures for the nervous patient, an opportunity to relax.

Furthermore, it is our opinion that all patients who fail to respond satisfactorily to the Sippy regime should be treated with aluminum hydroxide before resorting to surgery. At present, there is a tendency to advocate radical surgery for this type of patient. This is an admission that the older and simpler operations have not proved satisfactory. However, the present reports on subtotal gastrectomy do not tell us whether the final results will be superior to the simpler operations. The use of subtotal gastrectomy is comparatively recent in this country. It is to be remembered that one cannot accurately evaluate any form of treatment in peptic ulcer until a large number of patients have been carefully followed for five years or more. Although at the Peter Bent Brigham Hospital, we have been conservative in the use of this operation, we have encountered already, a few patients in whom a recurrence of ulcer has followed almost complete removal of the stomach.

Therefore, we believe that it is distinctly worth while to try aluminum hydroxide before attempting a subtotal gastrectomy. In 1934 (8), one of us stated the belief that it was preferable to treat these severe cases by medical means even though the results were somewhat unsatisfactory, rather than to submit a patient to the danger of a jejunal ulcer. The present evidence on the effect of colloidal aluminum hydroxide suggests that these patients can be carried along more satisfactorily by medicine than formerly. Certainly, it seems probable that hypersecretion may be kept under control as long as adequate amounts of the aluminum hydroxide are administered.

Postoperative jejunal ulcers have always been a

problem to our clinic because they have responded less well to therapy than the original ulcer. Two of the patients treated in this series had a jejunal ulcer and both have appeared to do better with the aluminum therapy than with the usual alkaline powders. Therefore, we look forward to studying the effect of aluminum hydroxide on this type of case more fully in the future. One of our patients had a marked retention which had been present over a considerable period of time. He was placed on the drip therapy for a period of three weeks with a decrease in the retention from 2300 cc. to 100 cc. This observation is of importance because one of our problems has been the treatment of obstruction in the presence of a hypersecretion. If medical treatment fails to control the acidity there is slight chance of improving the obstruction and surgery must be resorted to, with its ever present danger of a jejunal ulcer. The fact that treatment by aluminum hydroxide can overcome obstruction may relieve the physician's mind of the necessity of having to advocate surgery. Moreover, if one encounters patients whose obstruction does not respond to therapy, it will be possible to overcome the hypersecretion before attempting surgery and perhaps, by this means, can prevent or decrease the probable development of a jejunal ulcer.

Colloidal aluminum hydroxide is also useful for treating ulcer patients who show a tendency to form renal calculi. The drug is absorbed but slightly and does not interfere with the acid base balance. It proved to be very useful in treating the four patients of this series who had nephrolithiasis.

These studies show that colloidal aluminum hydroxide is a useful therapeutic agent in the treatment of peptic ulcer. It has three advantages:

1. Complete relief of pain is obtained within a short time after the onset of treatment.

Chart 6. The average number of units of hydrochloric acid secreted in response to histamine, by 12 patients, before and after treatment with aluminum hydroxide. These units are the product of the total acidity per 100 cubic centimeters of gastric juice, in terms of tenth normal sodium hydroxide and the volume of the gastric juice in cubic centimeters.

2. Complete neutralization of the gastric juice can be obtained in all patients.

3. It is not known to interfere with the general bodily chemistry.

Because its present cost is greater than the alkaline powders usually prescribed, one may wish to limit its use to specific indications. Furthermore, the question arises of why the drug inhibits the secretion of acid, and how long it is justifiable to use it in the individual case.

From the data presented by others there would seem to be no contraindication to its use so far as its absorption and effect on other organs is concerned. We have submitted two patients to operation after the use of the aluminum. One was a patient on the Surgical Service of the Peter Bent Brigham Hospital, to whom, with the permission of the surgeons, we gave the aluminum hydroxide drip for a period of 4 days before operation. The other was the patient with obstruction who had received the treatment for three weeks. Although he was improving, he desired surgery and because we were interested in observing the effect of the aluminum on the gastric mucous membrane, surgery was performed. Both had resections done and the gastric tissue studied histologically. No change could be seen in the gastric tissue.

SUMMARY AND CONCLUSIONS

Twelve patients with peptic ulcer have been treated by colloidal aluminum hydroxide. This was given orally or by a combination of a continuous drip and oral method. It was found that the gastric contents can be neutralized completely by this therapy. Relief of pain occurred within 24 hours. In addition to neutralizing the secreted acid, the drug decreased the titratable acidity. Patients with a marked hypersecretion were brought under satisfactory control. No adverse effects have been noted by the treatment. It is suggested that this form of therapy will be useful particularly in treating patients with a marked hypersecretion who formerly have been difficult to control by the usual alkaline powders.

DISCUSSION

DR. ALBERT F. R. ANDRESEN (Brooklyn, N. Y.): It was interesting to see how the speaker proved so conclusively that gastric acidity can be reduced by his method. However, it may be interesting to consider the relation between hyperacidity and ulcer.

Hyperacidity is undoubtedly not the cause of ulcer, because it is found in patients without ulcer and during the intervals between the occurrence of ulcers.

Hyperacidity does not interfere with the healing of ulcer, as we know from animal experiments showing rapid healing in the presence of acid, from observations in humans not treated by neutralization of acid and from the

X-ray proofs submitted to this Association by Lewis Gregory Cole several years ago, showing rapid and complete healing of ulcers without any treatment.

Hyperacidity is not the cause of pain in ulcer, as we know from the fact that pain does not occur during fractional gastric analysis when the high point of acidity is reached, but does occur when the stomach is empty or nearly empty and with reduced acidity from the fact that pains can be relieved if the patient takes acidified drinks in sufficient quantity to allow hunger contractions, and from the fact that pains do not occur during the intervals between ulcers, when the hyperacidity is still present.

Hyperacidity, therefore, not being a causative factor in ulcer, not being a cause of pain in ulcer and not interfering with the healing of ulcer, need not be considered in treating ulcer cases. Besides, an efficient neutralization of acid might conceivably interfere with digestion and with hormonal stimulation. I feel therefore that while the speaker has proved his point that acidity can be reduced by his method, its value in ulcer is not thereby proved.

DR. V. C. ROWLAND (Cleveland, Ohio): The aluminum hydroxide drip treatment in our hands has proved to be a procedure of definite value, especially for the case that does not respond to ambulatory treatment, as a special therapy before surgery and in the occasional case of recurrence after operation. By the use of the collapsible tube the discomfort is reduced to a minimum and on account of the valve-like action the flow of the aluminum hydroxide suspension is uniform and quite independent of gagging or straining on the part of the patient or any change in intragastric pressure. Only the occasional highly nervous patient has difficulty in retaining the tube for a ten-day period. Rather liberal use of sedatives and antispasmodics undoubtedly is of distinct help in the healing of ulcer as well as facilitating the use of the tube.

Pyloric obstruction from edema or spasm may be handled at first by the use of the Levin tube and, at intervals, the Wangenstein aspiration for removing retained gastric contents. The aspirating unit may be joined to the drip unit by a Y tube so that the flow can be reversed as often as is necessary to relieve nausea or distress. In this way much of the spasm and obstruction is relieved in a few days, and usually before the end of the week the collapsible tube may be used to replace the less comfortable Levin tube.

In hemorrhage cases the drip treatment has been instituted immediately on admission to the hospital or after transfusion and other emergency treatment. This is done with the idea of preventing acid digestion of a newly formed clot and recurrence of bleeding. Regular bland feedings are used at two hour intervals, thus enervating out the principles of Meulengraet plus the added principle of continuous neutralization. Vitamin C is also used in full dosage. The results in hemorrhage cases have been very good.

In suspected malignancy the tube treatment provided a more precise and expeditious therapeutic test than the routine management. This, of course, applies only to cases with a slight suspicion in which a second X-ray is in order after one therapeutic test treatment, and in no sense to take the place of surgery when there is a clear indication. A recent case in which the suspicion of malignancy remained in the X-ray after a ten day use of the tube treatment, but which proved to be a benign induration after resection showed advanced healing over the crater of the lesion. The deformity in the X-ray was largely due to the inflammatory thickening which radiated from the site of the ulcer for an inch or an inch and a half from the crater which was covered with epithelium.

The drip treatment, of course, cannot prevent recurrences or produce any more permanent results than are implied by a more complete degree of healing at the end of a period of continuous neutralization.

Like all other procedures it needs to be properly evaluated and to be used with discretion and individualization.

DR. VICTOR C. MYERS (Cleveland, Ohio): I was quite interested in Dr. Emery's remarks and think from our experience, I can agree with them, I have a few remarks I might make about aluminum hydroxide itself which may be of some help.

As a result of a paper which was presented a few years ago, we were called upon a number of times to suggest where one might obtain a satisfactory preparation of aluminum hydroxide. Personally I do not like to recommend a product not accepted by the Council of Pharmacy and Chemistry of the American Medical Association, and at present no product has been accepted. I am reasonably sure the Council would be glad to accept a product submitted to it under the name of colloidal aluminum hydroxide, without a trade name and without any false therapeutic claims.

We have recently examined a number of different preparations. To put them on a common basis, we have determined the total solids and then calculated the sodium chloride contents from the chloride titration. If one subtracts the weight of the NaCl from the total solids the residue should be aluminum hydroxide. If the preparation is a good one, the titrable acid combining power should equal the theoretical acid combining power calculated on the basis of the aluminum hydroxide (total solids less NaCl).

Apparently there are a good many preparations that do not yield the full acid combining power. If you heat a preparation of aluminum hydroxide for a few minutes, you will destroy most of its acid combining power. Granting that the value of aluminum hydroxide therapy is not entirely dependent upon its antacid properties, it should, nevertheless, have a theoretical acid combining power.

The reason for the titration of chloride is that the most logical method of preparing aluminum hydroxide is from aluminum chloride and sodium carbonate. The result of the chemical reaction should be aluminum hydroxide, some carbonic acid gas, and sodium chloride. It is simply necessary to wash out the excess of sodium chloride to obtain a satisfactory preparation of aluminum hydroxide.

A solid content of 5 to 6 per cent furnishes the best consistency, since the gel does not settle out. One of the preparations we examined had a lower solid content. It settled out, and was again evenly suspended only after considerable shaking. More uniform dosage is obtained when the gel is stiff enough to hold its consistency.

There are a number of preparations on the market, but it seems to me they all cost too much. For an eight-ounce bottle the ingredients cost about ten cents, and as you know the market price is very much more than this. The market price is unnecessarily high. I hope that these remarks may be of some help.

DR. ANDREW C. IVY (Chicago, Ill.): I think it might be appropriate here to summarize in about two minutes the results that we have obtained by treating Mann-Williamson dogs with aluminum hydroxide on a diet of parboiled meat, milk, and bread. This curve (using the blackboard) will represent the time of death with ulcer. We will say at this time 50 per cent of the dogs were dead of ulcer at ten weeks. That is a curve using forty dogs. If we give the animals a special diet of the same foods I mentioned, plus ground pancreas, liver, and syrup, we get a curve that is flatter, like that.

We took approximately twenty dogs on this special diet, and we gave them aluminum hydroxide four times a day, in the morning, at noon, about six o'clock at night, and about eleven o'clock at night. We found that the dose of aluminum we gave produced neutralization of free acid for a little longer than an hour on that regime, and our curve was about like that.

The early part of the curve was higher and the latter part a little lower than the control. There was not a great deal of difference.

We thought that we might obtain better results if we

gave a dose of aluminum hydroxide every hour, so as to assure complete neutralization of free acid; so we medicated the dogs every hour from seven in the morning until seven at night and gave a dose at ten o'clock and at midnight, and our survival curve was like that (laughter); in other words, the administration of the aluminum hydroxide cream took away the beneficial effects of the special diet, and we thought that that might be due to the possibility that the aluminum hydroxide was inactivating some enzymes in the pancreas, because a Mann-Williamson dog suffers a pancreatic deficiency. We studied that and found the aluminum hydroxide did not interfere with the enzyme action.

What we believe happened is this, and this is the prime suggestion which comes out of our work: We would not conclude that aluminum hydroxide therapy is of no value in the treatment of peptic ulcer in man from this work, but we would conclude that aluminum hydroxide is contraindicated in the presence of biliary or pancreatic deficiency on the basis of this theoretical consideration. When aluminum hydroxide interacts with acid in the stomach, aluminum chloride is formed, and we know that aluminum chloride is irritating to the intestine. Normally it would be reconverted to the hydroxide or an insoluble aluminum compound if plenty of alkali is present but, if not, then the aluminum chloride will irritate. There is another thing we must keep in mind in this type of therapy, that is a finding which the Remsen board seemed to agree on, namely, that aluminum increases the phosphate loss in the feces.

We are at the present time trying out an aluminum phosphate cream to see what it does. We have obtained results on only two dogs so far, but the results are encouraging; but, you can't get encouraged or enthusiastic about the results on two dogs any more than you can on two patients.

DR. HENRY A. RAFSKY (New York, N. Y.): I am inclined to agree with Dr. Andresen in his concept that the acidity does not play such an important role in the treatment of peptic ulcer. One year ago, before this society, I stated that the secretory response in peptic ulcer was a better diagnostic index than a therapeutic guide. I have studied the histamine response in ulcer patients when they first came to the hospital, before any therapy was tried and again just before they left the hospital. I did not see any material difference in the acid curves when the patients had severe symptoms and when they became symptom free. Being a protégé of Dr. Max Einhorn, I have observed for many years the results of treating ulcer patients with duodenal alimentation, in which practically no attention was paid to the acid factor. Excellent results were noted in most of these patients when they were hospitalized and treated by this method. Patients with hemorrhages as well as those with inflammatory pyloric obstruction were also treated with the duodenal tube.

In reference to Dr. Emery's statement regarding the volume of the gastric secretion, I wish to state that in comparing the acid curve and volume of the gastric secretion in normal individuals with high acidity and in patients with peptic ulcer, I noticed the following: In the normal patients the acid curves were high but the volumes were low. In ulcer patients the acid curves were high and the volumes were also correspondingly increased. Dr. Emery observed a high volume in his patients after treatment. This, I think is the crux of ulcer treatment, for unless we find some therapeutic measure which will keep the volume of the gastric secretion down in ulcer patients, we have not struck at the basic principle of ulcer therapy.

DR. MARTIN E. REHFUSS (Philadelphia, Pa.): Everybody is trying the blackboard, so I think I will try it, too. I noticed that the whole discussion this afternoon has resolved about the question of acid; in other words, the control of acid. The control of acid implies the ab-

normal formation of acid or at least acid as the cause or principal factor in the further formation of ulcer.

I would be very certain to follow these things if it were not for the fact that we spent, Dr. Hawke and a number of chemists and myself, some eight years in studying the acid curves of normal people. We had two hundred normal men. We studied the acid curves of two hundred normal individuals, and we found there is a tremendous normal variation in acid.

About 40 per cent have relatively high acid and a tendency to hypersecretion, and 35 per cent of normal individuals between twenty and twenty-five have a relatively low acid output. I personally believe that the acid response of an individual is as characteristic of that individual as the nose on his face.

I don't believe—and we found repeatedly, that we could control this free acid in the treatment of ulcer—we could control it with this drip and with kaolin and with alkalis, and the greatest combining substance of all is food, but there are only about twenty different diets for the control of ulcer, and it is a chronic disease, and if you keep them on an unbalanced diet too long, you are likely to get avitaminosis.

In the first place, we believe that the cause of ulcer is not acid but the cause of ulcer, like cirrhosis of the liver, must be a sensitization of the gastric cell by something.

All our experimental work shows that first cell death and then digestion and erosion by acid. The patient comes to us because he has an ulcer. He wants that ulcer healed. He doesn't want his secretion altered, necessarily.

Anything that will control the secretion long enough to permit that ulcer to heal is the logical thing.

At Jefferson we have been using in the wards this drip and we have been checking them very carefully and we have had very good results for the period in which the drip was used. We have kept it as long as eighteen days. We have succeeded in healing enormous ulcers insofar as the demonstration of the lesion by X-ray examination and in one or two instances by gastroscopy revealed. In the intervening period this method served to control the lesion, but my experience shows in all probability two or three weeks later they will revert back to their individual type of secretion; therefore, I feel if this method is used for two, or three, or four weeks in gastric ulcer especially (you don't see the same changes in duodenal ulcer), this method, if it will control the situation so the original area of necrosis or whatnot can be healed, then it has done the work which it was intended to do and for that reason I, for one, believe we can't expect a change in the secretory output of an individual.

In our experience healing does take place with this method.

DR. BURRILL B. CROHN (New York, N. Y.): I have no personal experience with the aluminum hydroxide drip as a method of treatment for ulcer, but I should like to ask Dr. Emery why the principles of Dr. Winkelstein's milk drip do not answer all the requirements represented by the aluminum drip; has not the milk drip the same value of neutralizing acidity, day and night, and doesn't it cover in addition the nutritive requirements of an ulcer patient on a minimum diet? Does it not answer the criticisms of Dr. Ivy insofar as there is no possible secondary or byeffect of the breakdown of aluminum hydroxide into aluminum chloride?

From the experience I have had with the milk drip, it

answers all these and gives satisfactory results. I do not suppose it alters eventually the acid curve any more than does the aluminum hydroxide.

For years it has been known that the ulcer patient's secretory curve is not altered. Nothing alters his acidity curve which is characteristic for the individual. During the course of treatment the ulcer heals under an anacid substance. It heals, though the acid may persist.

I should like to ask Dr. Emery if he has experimented with the milk drip and whether he feels that the aluminum hydroxide has any advantage over the milk drip for the same purpose?

DR. EDWARD S. EMERY, Jr. (Boston, Mass., closing the discussion): I think I will answer Dr. Crohn first. I don't know that it has any advantage over the milk and soda drip. Personally I have not used the milk and soda drip. We tried this out because it has been reported that the secretion of hydrochloric acid remains lower than before treatment, for several months after the treatment was started. If that should be true, which I don't know about, because we haven't had an opportunity to study that point ourselves, then we have a method which will accomplish something which the milk and alkaline drip does not. But I can't answer Dr. Crohn's question.

The rest of the discussion seems to come down to the relationship of hydrochloric acid to ulcer.

It seems to me that it is perfectly clear. On the one hand, there is evidence that the acid doesn't change with the periods of activity and periods of quiescence of an ulcer. If that is true, then there must be some other factor in addition to the acid, otherwise a normal stomach would be digested by its own acid. On the other hand, we have the evidence as ably presented by Lindau and Wulff, and others, that if hydrochloric acid strikes tissue which doesn't usually receive it, then a peptic ulcer develops. Therefore, it seems to me we have conclusive evidence that hydrochloric acid is related to a peptic ulcer in some way.

Finally, the question of the Mann-Williamson dogs—I think there has been a lot of misunderstanding about that. Mann and Williamson went out to prove or disprove the relationship of hydrochloric acid to peptic ulcer, and that is what it seems to me they did do. They were able to show that unneutralized hydrochloric acid resulted in a peptic ulcer in an animal, but that if you neutralized the hydrochloric acid, the ulcer did not develop. They didn't try to say that that was the mode of production of an ulcer in a human being, and certainly we have got a great deal of evidence, or at least we know that the procedure of the Mann-Williamson operation does a great deal more than just result in an unneutralized gastric juice. Hence, it seems to me, that all the literature, or all the data we have at the present time makes it pretty clear that something happens to break down the normal resistance of the mucous membrane to hydrochloric acid.

I don't know personally whether this treatment is going to be of any more value than the means of producing rapid relief, as Dr. Rehfsuss has just said. I think it is useful because we have been able to bring patients under control, in the way of relieving their pain more rapidly and in a more comfortable way than we have been able to do with any other kind of treatment. If it serves nothing more than to take care of the patient until such a time as the normal healing process is accomplished through adequate diet and general good hygienic treatment, then I think it may prove useful.

The Level of Ascorbic Acid in the Blood and Urine of Patients with Peptic Ulcer*

By

DONALD T. CHAMBERLIN, M.D.

and

H. J. PERKIN, M.A.

BOSTON, MASSACHUSETTS

SINCE 1935 the literature has contained numerous articles dealing with the metabolism of Vitamin C. The majority of investigators (2, 6, 7, 10) finding a lower than normal excretion and blood level of ascorbic acid in a group of patients, have adopted the view that a deficiency of Vitamin C was present in these cases. In fact, it has been assumed that a state of asymptomatic scurvy is present in patients with peptic ulcer because of the low excretion levels found. In this connection it is worthy of note that Finkel (5) found the excretion of ascorbic acid to be low in a group of hospital patients with different conditions, but was unable to correlate this finding with any clinical phenomenon. Rivers and Carlson (4) found that in cases of hemorrhage from the gastro-intestinal tract, the ascorbic acid levels in blood and urine were low. They pointed out that the customary diet given to patients with peptic ulcer is likely to be deficient in Vitamin C. Lazarus (10) found Vitamin C deficiency in a group of fifteen patients with peptic ulcer, thirteen of whom had a history of bleeding or were bleeding on admission to the hospital. However, a smaller number of non-hemorrhaging patients also had low ascorbic acid levels of blood and urine.

The purpose of this study was to gain more information concerning this apparent deficiency and to ascertain the amount of additional ascorbic acid necessary to maintain normal levels of excretion in patients with peptic ulcer.

It has been the policy of the Gastro-Intestinal Department of the Lahey Clinic to give orange juice to patients in the hospital for ulcer management. These patients receive two ounces of orange juice diluted with six ounces of water in divided amounts throughout the day. No cases of clinical scurvy have been noted in patients on this regimen. All the patients received hourly doses of an antacid, either colloidal alumina gel (amphojel) or tri-basic calcium phosphate (tricalate).

By our methods, the twenty-four-hour urine excretion of ascorbic acid in normal individuals was found to be from 17 to 25 mg. per cent. These values are in keeping with those reported by others (2, 3, 4, 5). Analysis of the first morning urine specimen has been shown to equal $\frac{1}{4}$ to $\frac{1}{8}$ of the twenty-four-hour amount. This appeared to be a relatively constant fraction of the total twenty-four-hour excretion, so as a matter of convenience was used in this study. Blood for ascorbic acid analysis was taken from patients in the fasting state. The methods employed for urine analysis were those described by Harris and Ray (2) and that for blood by Farmer and Abt. All analyses

were carried out as soon as possible after the sample was secured. In all, 808 estimations were made on 264 patients.

The blood Vitamin C was estimated in twenty-seven cases of peptic ulcer. In many of these patients, the analyses were done daily for the period of a week in order to determine the daily variation. The urine Vitamin C** in these cases as well as in an additional thirty-nine cases was similarly analyzed. The same procedures were followed in a group of sixteen normal individuals. The results are shown in Table I and Table II.

TABLE I

Ascorbic acid in the blood of ulcer cases and normals

	No. of Cases	No. of Estimations	Range of Values in mg. %	Average in mg. %	Less Than 1 mg. %
Ulcer	27	86	0.30—1.44	0.63	20
Normal	16	20	0.58—1.38	1.44	3

From Tables I and II, it will be seen that there was a considerable overlapping of the results; the average level of Vitamin C in the blood and urine of ulcer patients was appreciably less than that of normal individuals. In patients on whom the blood and urine levels were followed from day to day, fluctuations amounting to 100 per cent were found. Furthermore,

TABLE II

Ascorbic acid in the urine of ulcer cases and normals

	No. of Cases	No. of Estimations	Range of Values in mg. %	Average in mg. %	Less Than 2.50 mg. %
Ulcer	66	290	0.10—5.10	1.20	46
Normal	30	51	1.30—9.20	4.05	6

the variations in the amount of ascorbic acid in the urine did not necessarily parallel that of the blood in the same patient, nor could these variations be accounted for by the diet.

The fact that the patients with peptic ulcer were confined to bed while the normal group were engaged in their usual activities may be an influencing factor in the results found. In order to gain more information concerning this point, similar procedures were

*From the Department of Gastro-Enterology and the Research Foundation, Lahey Clinic, Boston, Mass

**First morning urine

followed in a study of the urine levels of ascorbic acid in exophthalmic goiter cases, and in patients receiving bed treatment for functional disease of the digestive tract. The diet of both these groups was considered adequate in Vitamin C. The results are shown in Table III.

TABLE III

Ascorbic acid in the urine of cases of exophthalmic goiter and functional digestive diseases

	No. of Cases	No. of Estimations	Range of Values in mg. %	Average in mg. %	Less Than 2.50 mg. %
Exophthalmic Goiter	25	25	0.35—9.84	2.60	16
Functional	9	23	0.50—7.20	2.10	21

From Table III it will be seen that the Vitamin C excretion in these groups of patients who were confined to bed was similarly subnormal. The decreased levels of ascorbic acid in the urine of exophthalmic goiter patients has been noted by others.

It is our opinion that the above results cannot be considered as conclusive evidence that an actual Vitamin C deficiency was present in the cases of peptic ulcer studied (Tables I and II). Since it is believed that patients having an actual deficiency of Vitamin C require relatively larger amounts of ascorbic acid before evidence of the Vitamin is found in the urine, we attempted to test the response of ulcer patients to the daily administration of Vitamin C by following the excretion of ascorbic acid from day to day. Preliminary work revealed that appreciable amounts of ascorbic acid appeared in the morning urine in all cases when 400 mg. of Vitamin C* was given intravenously the previous night. Lesser amounts of Vitamin C produced no rise in ascorbic acid in the morning urine of most cases of peptic ulcer although normal individuals showed an appreciable effect from the administration of 300 mg. Accordingly, 300 mg. was given intravenously each night and the first morning specimen of urine analyzed for ascorbic acid in an additional group of cases. The results are shown in Table IV.

TABLE IV

Ascorbic acid in the a.m. urine of cases receiving 300 mg. of vitamin C intravenously each day at 10 p.m.—average values in mg. % for the groups are given

	No. of Cases	Days Followed:					
		0	1	2	3	4	5
Ulcer	11	1.97	6.17	8.87	21.4	29.4	39.9
Normal	2	4.20	91.0	162	—	—	—

As will be seen from Table IV, the normal individuals responded to the Vitamin C injections by excreting greater amounts of ascorbic acid than did the ulcer patients. In order to test the influence of the method of administration, the same dose (300 mg. of Vitamin C*) was given orally in a different group of patients and the urine excretion followed. An ad-

ditional group of patients confined to bed for functional digestive disorders was added to this series. The results are shown in Table V.

From the above tables it will be seen (Tables IV and V) that the intravenous administration of Vitamin C was more effective in increasing the amount of ascorbic acid in the urine of ulcer patients than was the same dose given by mouth. In normal individuals the method of administration did not appear to be a factor in the amount of vitamin excreted. Regardless of the method by which the Vitamin C was given, the response, as measured by the urine excretion of ascorbic acid, was greater in the functional disease group and normal group than in patients with peptic ulcer.

Since 300 mg. of Vitamin C given orally each night at 10 p.m. increased the morning urinary excretion of ascorbic acid (see Table V) the same dose was given in divided portions of 100 mg. throughout the day and the urinary excretion followed in an additional group of cases. The results of this series of cases are shown in Table VI.

As will be seen in Table VI, the general response to 300 mg. of Vitamin C given in divided doses was similar to that when the same amount was given in a single dose. The results as a whole lend credence to the view that the requirement of Vitamin C is greater in patients with peptic ulcer than individuals not so affected.

Since 100 mg. of Vitamin C given orally three times a day resulted in an excess excretion, it seemed reasonable to try smaller doses. Accordingly 50 mg. was given orally four times a day to an additional group of patients the results of which are shown in Table VII.

It would appear from the results of Table VII that 50 mg. of Vitamin C given orally four times a day furnishes an adequate amount for peptic ulcer patients whose requirements of Vitamin C are greater than those of normal individuals. Amounts greater than this are excreted in the urine.

DISCUSSION

Individuals showed wide fluctuations in their daily excretion of ascorbic acid, both patients with peptic ulcer and the controls. These fluctuations occurred in the group studied, who received no ascorbic acid, and

in the various groups on different doses. It was interesting to note the prompt fall from a high concentration to a subnormal value in any case in which the dose of ascorbic acid was withheld for one day. We were unable to account for these variations in excretion, as the diet, medication, and method of determination of ascorbic acid remained the same in all cases.

We believe that the extent of Vitamin C deficiency

*The Vitamin C used in this work was kindly supplied by Hoffman-La Roche, Inc.

in any one case cannot be ascertained from one urine analysis, but that the daily excretion levels must be studied for at least five days, and the response to dosage with ascorbic acid watched. (Other investigators (1) have been able to correlate the amount of Vitamin C in the diet over a period of months or

C results in an earlier and greater excretion of ascorbic acid in the urine in normal individuals, and patients on other dietary management, than in patients with peptic ulcer.

3. The amount of additional Vitamin C required to raise the excretion of ascorbic acid to normal in

TABLE V

Ascorbic acid in the a.m. urine of cases receiving 300 mg. of vitamin C orally each day at 10 p.m.—average values in mg. for the groups are given

	No. of Cases	Days Followed:								
		0	1	2	3	4	5	6	7	8
Ulcer	11	2.00	2.62	6.73	16.2	7.31	17.5	13.05	13.4	30.8
Functional	6	1.02	4.56	4.87	27.6	58.0	37.3	21.2	55.5	51.2
Normal	3	4.05	119	104	258	—	—	—	—	—

years, with the plasma ascorbic acid, apparently making only one determination in each case. Since the daily variation may be great, and since the plasma ascorbic acid does not necessarily parallel the urinary excretion level, we were unable to corroborate this work).

The administration of Vitamin C to the peptic ulcer patients did not alter in any evident manner the clinical course during hospitalization. They felt as well but apparently no better than patients on ulcer or other dietary management who did not receive Vitamin C. The free hydrochloric acid was not influenced by the ascorbic acid given. There appeared to be no difference as to the antacid used in the amount of ascorbic acid excreted, whether used singly, in combination, or if a change from one to the other was made. The length of time required to produce a significant rise of ascorbic acid in the urine could not be correlated with any factor in the course of the disease, the age, sex, diet or previous therapy. Patients with a history or presence of hemorrhage showed results indistinguishable from those without hemorrhage. Patients who had occult blood in the stool during the first few days of therapy could not be identified from others by the urine level of Vitamin C either before or during Vitamin C medication.

SUMMARY AND CONCLUSIONS

1. Evidence is presented to show that hospitalized patients on ulcer management have lower levels of ascorbic acid in the blood and urine than normal individuals or patients with functional digestive disorders.

2. Evidence suggesting that peptic ulcer patients require greater amount of ascorbic acid is demonstrated by the fact that daily medication of Vitamin

patients with peptic ulcer appears to be 50 mg. four times a day.

4. There appears to be no clinical evidence that ascorbic acid in doses large enough to maintain the excretion at the normal level is of any value in the treatment of patients with peptic ulcer with or without hemorrhage.

5. It is suggested that the metabolism of Vitamin C is influenced by activity and that lower blood and urine values are found in patients resting in bed than in active individuals.

DISCUSSION

DR. SARA M. JORDAN (Boston, Mass.): Mr. Chairman: I am really not at all qualified to discuss this paper because I am not a biochemist. My only excuse is that it was done under the wing of the Gastro-Enterological Department at our clinic by Dr. Chamberlin, a member of the Department, and our research chemist, Mr. Perkin; however, there are a few facts which seem to me rather suggestive from both the experimental and the clinical point of view. The first was this day-to-day variation in the results which it seems to me must be very carefully taken into account when we talk about sub-clinical scurvy as an experimental condition.

Secondly, the fact that rest and activity seemed to play a part. That is perhaps a precocious conclusion, but at

TABLE VI

Ascorbic acid in the urine of cases receiving 100 mg. of vitamin C orally three times a day—average values in mg. for the groups are given

	No. of Cases	Days Followed:							
		0	1	2	3	4	5	6	7
Peptic Ulcer	3	1.60	2.10	2.35	2.75	3.17	10.6	23.2	28.8
Functional	3	2.10	3.16	4.52	6.97	31.7	24.9	24.0	29.0
Normal	6	4.05	6.70	13.2	37.4	13.6	61.8	37.1	—

least it is suggested by these data. The metabolic demands apparently are a factor in the findings of the cevitamic acid study.

Thirdly, it is interesting to note the fact that the presence of hemorrhage appeared to play no part in the variations which were found here.

Chamberlin's paper, 20 per cent of the people he classified as normal were low in C, and of his functional group, more than 20 per cent were low in C; in other words, it seems to me it is a difficult problem to combat functional or degenerative or infectious diseases unless we fuel the body properly.

TABLE VII

Ascorbic acid in the n.m. urine of cases receiving 50 mg. of vitamin C orally four times a day—average values in mg. for the groups are given

	No. of Cases	Days Followed:						
		0	1	2	3	4	5	6
Peptic Ulcer	7	1.56	1.60	1.51	3.23	2.51	6.75	5.20
Functional	3	1.00	1.76	1.41	2.44	3.88	9.00	6.75
Normal	4	3.38	8.92	22.4	25.9	16.8	15.7	—

From the clinical point of view it was suggested that excessive vitamin therapy was certainly useless. It was also suggested by the findings that vitamin therapy, bringing the cevitamic acid to normal, was a desirable thing. Whether or not it has any effect on the healing of the ulcer, we who used to give the low vitamin diets perhaps may doubt, because we certainly felt that in the days when we are now sure we did not have enough Vitamin C in the diet, the ulcer healing did take place.

In this matter it would be of interest to ask Dr. Brown, who was good enough to bring with him a slide showing the vitamin content of various diets, from the Mayo Clinic, to show the slide and discuss the paper.

Finally, one little point which I think is of interest, and that is the fact that during this study Dr. Chamberlin and Mr. Perkin checked the vitamin content of hot orange juice. It is our custom to give orange juice diluted with hot water, because we feel it is better tolerated by the ulcer patient, and sometimes by other patients. Occasionally we hear the criticism that orange juice loses its vitamin qualities thereby. Dr. Chamberlin and Mr. Perkins checked that and found that the orange juice itself could be brought to the boiling point without losing its vitamin qualities and, secondly, it could be diluted with hot water and still retain all of its Vitamin C.

DR. PHILIP W. BROWN (Rochester, Minn.): I always smile at the individual who comes enlisting somewhere and didn't plan to talk or do anything else and, when he is asked to say something, has a whole pocketful of slides. (Laughter)

My excuse for this slide is that I was talking at the Mississippi State Meeting the week before last, on nutritional problems, and Miss Mary Foley, of the Dietetic School of Nursing, had prepared this slide for me as part of that talk. I am offering this slide not in any manner of means discussing the etiology or therapy of ulcer, of which I know nothing, but merely to emphasize a point which apparently has been thought of more by the farmer and by his stock breeder, perhaps, than by us.

I think in these sacred walls here we can talk about diets, but when we get outside the walls, there is no one word that gives us more pain than the discussion of diets by all people who come into the office. (Laughter)

(Slide) It is interesting to note on this slide the low levels of vitamins in these particular diets. The ulcer diet is particularly low in B and in C. I will leave the significance of that to you. The high vitamin diet was of particularly great disappointment because it is high only in A and D, and I am not sure that we need that much A and D.

As you follow along in the long variety of gastro-intestinal conditions which are not sprue, nor pellagra, nor ulcer, nor true ulcerative colitis, it is amazing how deficient most of these people live; as you will notice in Dr.

DR. EDWARD S. EMERY, Jr. (Boston, Mass.): I should like to say a few words about this because we have also been interested in this subject.

It is generally agreed by what may be called the experts in this line that the blood serum, or the blood plasma levels have no relationship to the degree of saturation, that is the amount of Vitamin C in the body we have also found this; for example, one patient which we studied required only 600 milligrams of ascorbic acid to become saturated, although his blood plasma level was 0.6; whereas another one whose blood plasma was 0.7, required 1500 milligrams of Vitamin C.

Secondly, it is also agreed that there is no relationship between the blood values and the spill in the urine. We had one patient, for example, whose blood value was 0.6, who spilled 20 milligrams without any added Vitamin C; and another, 1.36, who spilled none in the urine.

Dr. Ralle showed this morning that there is no threshold value for the blood level. Therefore, we used the method of Heineman and Van Eekelen, whereby they saturate their patients with Vitamin C, giving large doses by mouth until it spills over, and then wait ten days, saturate them again, and find how much it takes to produce another spill. By this means we found that the daily requirement of the peptic ulcer patient, appears to be a little higher than the normal. The normal requirements, as given by Van Eekelen and Heineman, are 0.85 milligrams per kilogram of body weight per day.

In the ulcer patients we have studied, it has varied from 0.91 to 1.2, with an average of 1.02. Therefore, this would suggest, that ulcer patients have a slightly higher requirement for Vitamin C, but it is of no importance because an extra orange each day will take care of the deficit.

DR. MARTIN G. VORHAUS (New York, N. Y.): A word of caution as we go into the discussion of the vitamins: It is well to recall that we are discussing a vitamin which is water soluble and probably not stored in the body. Unless we know a great deal about the previous diets of these ulcer patients, as we do in experimental animals, it is somewhat of an inaccuracy to speak of saturation of any water soluble vitamin.

Dr. Chamberlin pointed out that he studied these cases for eight days, and at the end of that time these patients were still not saturated. The degree of saturation has been stated in the terms of one unknown, i.e. How long was any given patient on a subminimal intake? But other unknowns have not been mentioned, namely—the amount of any vitamin necessary for any given patient, which is modified by the basal metabolism of the individual, infection, the amount of work and other factors. Unless we

know all the variables in patients we cannot draw adequate conclusions as to their individual vitamin requirement.

DR. DONALD T. CHAMBERLIN (Boston, Mass., closing the discussion): I wish to thank the discussers. First I should like to speak about the point of saturation. There must be some other factor besides simple saturation, since 200 milligrams given per day give a significant rise

on the same diet that 300 milligrams do. There is much yet to be learned about the metabolism of Vitamin C and I believe until we know how the normal behaves, all the results so far in any group of patients with any disease are not significant. Until we know whether an active individual on his feet, with an adequate diet, has the same Vitamin C blood and urine levels after he has been in bed, on that same diet, we cannot be sure that these results mean anything.

Vagotomy Plus Partial Gastrectomy for Duodenal Ulcer*

By

ASHER WINKELSTEIN, M.D.

and

ALBERT A. BERG, M.D.
NEW YORK, NEW YORK

WHILE the cause of peptic ulcer is still unknown, there is today a strong tendency to regard the disease as a nervous affection. There is a mass of accumulated evidence that it is caused in most cases by a psychogenic disturbance. The nervous pathway presumably is the vegetative nervous system chiefly the vagus which acts by producing increased motor and secretory activities leading eventually to the ulcer disease.

Whatever the ultimate cause of ulcer may be, all observers seem to agree that the acid factor is of central importance. On several occasions we have presented our studies on the acid factor before the Association. We demonstrated, using an orange test meal, that the nervous phase of gastric secretion was very high in duodenal ulcer and that the chemical phase was low to normal both in gastric and duodenal ulcer. We also demonstrated that the harmful nocturnal acid secretion was greatly increased in peptic ulcer. According to Babkin, this is also a vagally conditioned phenomenon. Because of these observations and the fact that peptic ulcer, either primary ulcer or post-operative recurrent ulcer, does not in our experience occur in an achlorhydric stomach, we advocated milk drip to continuously neutralize the day and night secretion medically and partial gastrectomy to produce a harmless achlorhydria without recurrence surgically. As a result of many years of experience with both methods we recommend them strongly in the therapy of peptic ulcer.

It is our purpose today to present the important problem of recurrences after partial gastrectomy. It has been our experience that partial gastrectomy invariably produces a true achlorhydria without recurrences in patients with gastric ulcer on the lesser curvature. In duodenal (or juxtapiyloric) ulcer on the other hand, it produces an apparent achlorhydria only in 50% of the cases despite extensive resection. It is in the group with retained acid that we have encountered recurrent jejunal ulcers. In order to avoid reoperation for peptic ulcer an apparent or true achlorhydria is the ideal state. We have not seen a recurrent ulcer when there is a post-operative achlorhydria. It is probable that the most important factors in the

question of the post-operative acidity are the following: (1) The removal of the antrum (abolishes the chemical phase) (2) the amount of fundus secretory tissue removed (extent of resection) (3) the duodenal regurgitation (4) the vagus nerve irritability and (5) the amount of gastritis present. The first three factors are physiologic and the last two are pathologic. Therefore, the fact that subphrenic vagotomy plus partial gastrectomy in dogs may not produce an achlorhydria in a Pavlov pouch should not be an argument against such a procedure in the human where the additional pathologic processes mentioned above come into play.

It is our chief purpose here to demonstrate the acidity in peptic ulcer patients before and after partial gastrectomy with particular reference to the problem of preventing post-operative recurrences in the patients with duodenal ulcer with a high pre-operative acidity.

Chart 1. (1) Composite curve of free HCl in 10 gastric ulcers with high acid before operation. (2) Composite curve of free HCl in the same 10 gastric ulcers after partial gastrectomy without vagotomy. (3 weeks).

Note: In all gastric ulcers at the angle irrespective as to whether the acid is high before operation as in this curve or low, there is practically always an immediate and late true achlorhydria. (This results from the removal of the antrum, high resection, inhibition by gastritis or from the intestine).

Chart 2. (1) Composite curve of free HCl in 38 duodenal ulcers before operation. (2) Composite curve of free HCl in the same 38 duodenal ulcers, 3 weeks after partial gastrectomy (without vagotomy).

Note: Partial gastrectomy alone in duodenal ulcers with high pre-operative free HCl produced an immediate post-operative achlorhydria only in 3 cases. (Persistence of vagal hyperirritability with retained secretory tissue).

Briefly our studies have demonstrated the following:

1. Patients with gastric ulcer who have either a high or a low preoperative free HCl practically invariably have an achlorhydria without recurrences post-operatively. (Chart I)

2. Patients with duodenal (or juxtapiyloric) ulcer with a high pre-operative acidity (over 60—chiefly 70-100) rarely get an achlorhydria (immediate or late) after partial gastrectomy. (Charts II and III)

3. Patients with duodenal (or juxtapiyloric ulcer) with a normal free HCl (20-40) pre-operatively in a large per cent of the cases develop a post-operative achlorhydria without recurrences. Chart IV)

Chart 3. (1) Composite curve of free HCl in 24 cases of duodenal ulcer with a very high pre-operative acidity. (2) Composite curve of free HCl in the same 24 cases after partial gastrectomy without vagotomy. All the cases in this group had repeated fractional test meals from 1½ to 4 years post-operatively. Only 1 patient in this group developed an achlorhydria 9 months after operation. 4 other patients had an immediate post-operative achlorhydria.

Note: In the entire group of duodenal ulcers, 59 cases, all with very high pre-operative acidity, only 8 (13%) developed a post-operative achlorhydria. Apparently partial gastrectomy alone in patients with a high free pre-operative acidity produces achlorhydria in duodenal ulcers only in a small per cent of cases.

Chart 4. (1) Composite curve of free HCl in 23 duodenal ulcers before operation with low acidity (20-40 free HCl). (2) Composite curve of free HCl in 7 of these cases (trace of free HCl persists). (After partial gastrectomy without vagotomy). (3) Composite curve of free HCl in 16 of these cases—all 16 developed an immediate achlorhydria which persisted. (After partial gastrectomy without vagotomy).

Note: In 23 cases of duodenal ulcer with a low normal free HCl (20-40) 16 or 70%, developed an immediate achlorhydria. Apparently partial gastrectomy alone will produce an achlorhydria in most duodenal ulcers with a low preoperative acidity.

4. Patients with a high pre-operative acidity in duodenal ulcer form the group in which post-operative recurrent jejunal ulcer occurs. (Chart V)

5. Subphrenic anterior vagotomy plus partial gastrectomy produces an achlorhydria (immediately or later) in most duodenal ulcer patients with a very high pre-operative acidity. (Charts VI and VII)

6. It is probable but not proved that the addition of this procedure, viz; anterior vagotomy, may prevent almost entirely post-operative recurrences in duodenal ulcer.

7. Because of the fact that gastro-enterostomy heals duodenal ulcer but favors the production of jejunal ulcer (probably by the effect of the increased gastric motor and secretory activities on the jejunum) gastro-enterostomy plus subphrenic vagotomy has been advocated and used in the treatment of a small, selected group of duodenal ulcers.

8. Finally, a renewed, careful study of the technique, indications, and results of subphrenic anterior or anterior plus posterior vagotomy alone or in combination with other surgical procedures in the therapy of peptic ulcer seems highly desirable.

DISCUSSION

DR. IRVIN ABELL (Louisville, Ky.): I really feel incompetent to discuss the material presented by the essayist since we have had no personal experience with vagotomy and but a comparatively limited one with massive resection in duodenal ulcer. With your indulgence I will present our reasons for what may be regarded on the part of the essayist as ultraconservatism in our clinic. We regard peptic ulcer as primarily a medical problem, assuming surgical significance only with its complications, sequelae and intractable chronicity. These are perforations, repeated bleeding and obstruction due to cicatrization. A single massive hemorrhage is not regarded as an indication for operation: a chance for healing under medical treatment should be afforded until further bleeding or chronicity demonstrates its futility. Chronicity in spite of appropriate treatment is accepted as a failure of the latter and an indication for operation. Since duodenal ulcers do not show a tendency to malignant degeneration, it has been argued that chronicity alone does not justify resort to operation. The danger of perforation, the menace of hemorrhage, the possibility of obstruction and the continued discomfort produced by the chronic ulcer, which

proves resistant to an intelligently planned medical treatment, afford sufficient grounds in our opinion to negate this assumption. The discussion this afternoon has confirmed our belief that the cause of duodenal ulcer remains submerged in obscurity, and furthermore that achlorhydria is not a sine qua non for healing. With these postulates

CHART V

Recurrent jejunal ulcers after partial gastrectomy without vagotomy

Name	Pre-operative Free HCl	Post-operative	Complication
Wyche	75	20	Jejunal ulcer, perforated. Ceased
Strongen	77	40	Jejunal ulcer with hemorrhage
Wevix	95	42	Jejunal ulcer, penetrating
Eisenberg	62	48	Jejunal ulcer, penetrating
Chose	60	78	Jejunal ulcer. Ceased
Clarín	60	88	Jejunal ulcer, penetrating
Berger	78	80	Jejunal ulcer, hemorrhage
Friedman	100	80	Jejunal ulcer, hemorrhage
Plotaky	130	52	Jejunal ulcer, hemorrhage
Beer	64	50	Jejunal ulcer, penetrating
Coopersmith	90	110	Jejunal ulcer, penetrating
Guarneri	24	30	Jejunal ulcer, penetrating
Zeis	75	73	Jejunal ulcer, penetrating

Note: In 13 cases with jejunal ulcer after partial gastrectomy for duodenal ulcer, all but one case had a high pre-operative free acidity. Is it possible that the addition of high, anterior subphrenic vagotomy in this group would have prevented or lessened the occurrence of jejunal ulcer by producing an achlorhydria?

established in our belief we have employed the more conservative operations, selecting for each individual case the one best suited for the correction of the pathology it presents. When the ulcer is situated on the anterior wall of the duodenum and the parts can be satisfactorily mobilized, excision of the ulcer with a modified pyloroplasty gives a mortality rate of approximately one per cent and a freedom from symptoms in approximately ninety per cent. When location of ulcer or fixation of the parts do not lend themselves to this procedure, destruction of the ulcer with the cautery combined with a posterior gastro-enterostomy will give approximately the same results as to mortality and relief of symptoms. With marked obstruction a posterior gastro-enterostomy may be done with reasonable safety and with reasonable assurance of relief. These conservative procedures will meet the indications in the majority of simple duodenal ulcers and the results obtained place the burden of proof upon advocates of other methods to show just cause for such advocacy. When the ulcers are multiple, and they are in from five to six per cent: when situated on the posterior wall, difficult of access and so calloused as to render healing difficult: and when so situated the ulcer has perforated into the head of the pancreas with fixation of the duodenum and pylorus to the latter organ, we have come to the resection of the duodenum and pylorus. The extent of the resection in such instances is determined by the local pathology, either a Billroth I or II as local conditions permit. We have not employed massive resections with the avowed intention of

producing achlorhydria, since this condition is neither essential for the healing of ulcer nor necessary in the prevention of recurrence: furthermore, permanent achlorhydria disrupts the physiology of digestion, the ultimate effects of which while still undetermined may conceivably be distressing. Since we have had this experience, namely, a low operative mortality and a high percentage of relief, we feel that conservative surgical procedures plus intelligent supervision on the part of the gastro-enterologist or internist, offer a method of treatment preferable to the more radical application of surgery in the treatment of duodenal ulcer.

DR. JULIUS FRIEDENWALD (Baltimore, Md.): Dr. Winkelstein and Dr. Berg have presented an important paper.

If hyperchlorhydria plays as important role in the etiology of ulcer as many of us maintain and as it is certainly largely involved in the prevention of its healing, any measures by means of which hyperacidity can be overcome and achylia brought about should be employed in order to effect complete healing.

It is interesting to learn from the work of Drs. Winkelstein and Berg that this can be accomplished by means of vagotomy in association with other surgical procedures.

In a series of experiments on dogs reported some years

Note: 26 cases of Duodenal Ulcer with very high pre-operative acidity. 16 developed an achlorhydria immediately and the other 10 developed an achlorhydria in 4 months to 3 years. All 26 cases followed for 4 to 9 years and in all cases were well. The vagotomy is apparently harmless.

ago by Dr. Feldman and myself, the observation was made that by means of vagotomy alone changes in the gastric secretion due to section of the vagus were inconstant and that there was likewise a general tendency for the secretion to return to normal after a time when diminished as the result of this operation.

CHART VII

Partial gastrectomy with anterior vagotomy for duodenal ulcer followed by persistent free acid

Name	Pre-operative Free HCl	Post-operative Free HCl		Follow-up
		Immediate	Late	
Wollinsky	83	30	1 yr. 30 2 yrs. 30	8 yrs. well
Hodes	95	20	6 mos. 22	5 yrs. well
Milner	74	20	7 mos. 10	6 yrs. well

Partial gastrectomy with anterior vagotomy for duodenal ulcer followed by persistent free acid (no follow-up)

Name	Pre-operative HCl	Post-operative HCl
Gilman	104	16
Morosi	104	30
Zawitz	75	50
In 5 cases followed up, the acid persisted but there were no recurrences. In 3 cases acid persisted (there was no follow-up)		
Summary:		
Total number of cases		34
(Immediate)		16
(Later)		10
Persistent Acid (for 4 months to 2 years)		5
Persistent Acid (no follow-up)		3

Conclusion: In duodenal ulcers with high pre-operative acidity, partial gastrectomy alone results in achlorhydria only in a small per cent of the cases (13%). In duodenal ulcers with high pre-operative acidity partial gastrectomy plus anterior subphrenic vagotomy is followed by achlorhydria in a high per cent of the cases (77%).

Similar results were obtained from subphrenic vagotomy as well as from section of other portions of the nerve. Due to this uncertainty it is possible that the very favorable results obtained by Drs. Winkelstein and Berg are due to the combined effect of the gastric operation and vagotomy.

DR. ALBERT J. SULLIVAN (New Haven, Conn.): A view was expressed earlier this afternoon that acid isn't the only factor in the production of ulcer and I submit that we are already approaching a point where we can begin to formulate a theory as to the mechanism behind the ulcer problem. We have the observations of Harvey Cushing that the hypothalamic lesions produce gastric ulcerations. We have studies of those interested in the personality of patients with ulcer, their driving dynamic personality which keeps them on the go all the time; that plays a role in the ulcer mechanism, and the report of Dr. Necheles last year, physiological experiments stressing the point that acetylcholine as liberated by the parasympathetic nervous system by stimulation of the vagus, may be the chemical mechanism of the production of peptic ulcer, and today we have further evidence given by Dr. Winkelstein that this vagus factor is important.

It is a very complicated mechanism; it isn't neurogenic,

purely neurogenic, or purely psychogenic, or purely the chemistry of the autonomic nervous system, but a combination of all three; and I wish to mention a very unusual case which I have had the opportunity of seeing, a patient with myotonia congenita, a disease resulting in a stiffness of the muscles caused by an excess of acetylcholine and that can be relieved by giving the patient quinine, which prevents the action of acetylcholine on the cells.

This patient had an intractable duodenal ulcer. His myotonia was relieved by quinine and so were his ulcer symptoms.

Purely on a theoretical basis I am using quinine in a small group of selected cases in an attempt to prevent ulcer recurrences. It is too early to even report on the results.

We have also used atropin to neutralize the chemical effect of vagus stimulation through a different mechanism, and I believe all we need are a few more facts to bridge the gaps between all these theories and we can soon have a complete, logical exposition for the mechanism of peptic ulcer.

DR. BORIS P. BABKIN (Montreal, Canada): I should like to discuss this paper from a physiological point of view. I must confess that to me such operations as, e.g., a subtotal gastrectomy or section of vagi does not look at all physiological. However, the aim of Dr. Winkelstein and Dr. Berg's operation was to diminish the gastric acidity, and it seems that the only sure surgical way to do it was that adopted by them. The justification for the anterior vagotomy is that at the cardia the anterior or left vagus is a mixed nerve, which contains fibres from the left and right cervical vagi. The mixing of the vagal fibres occurs above the diaphragm. Therefore the section of the left or anterior vagus branches at the cardia will diminish to a certain extent the secretion in all parts of the stomach.

I should like to ask Dr. Winkelstein how he explains that an ulcer reappears more often after the operation for duodenal ulcer than after the operation for gastric ulcer. I understand that during the operation for gastric ulcer a much greater part of the stomach is removed than during the operation for duodenal ulcer. However this does not seem to explain everything. La Barre (Bruxelles) showed, e.g. that the secretory function of the fundus, or "poch à air" as the French are calling it, is in normal conditions under a lesser vagal control than the same function of the corpus of the stomach. However, under certain circumstances the relations may change. This was demonstrated by La Barre in a following way. One dog has a gastric pouch formed from the fundus (poch à air), another possessed a pouch formed from the corpus. The gastric secretion was activated by means of insulin which stimulates the vagal centre in the brain. The corpus pouch responded to administration of insulin by a copious secretion already on the second day after the operation. The fundus pouch, on the other hand, required from two to three months to acquire the ability to secrete gastric juice under the influence of insulin. Since not so much organ is resected in the case of duodenal ulcer, than in the case of gastric ulcer, the secretory function of the vagus is, in the first case, very little affected by this operation or is more quickly restored than in the second case. But the possibility of the restoration of the vagal secretory function must be kept in mind.

DR. ASHER WINKELSTEIN (New York, N. Y., closing the discussion): I am indebted to the discussers for their interesting observations.

With reference to Dr. Abell's statement that achlorhydria may not be the sine qua non for the healing of ulcer, we feel definitely from a very long experience with a large series of surgical cases that it is definitely the sine qua non for the prevention of ulcer recurrences. In our

experience we have yet to see a true recurrent ulcer in the jejunum after a partial gastrectomy which is followed by a false or true achlorhydria.

Our experience with gastro-entrostomy is unfavorable. We found a high percentage of recurrences. We believe at present that partial gastrectomy is the operation of choice for gastric and duodenal ulcer. We believe that subsequent work may prove that certain cases of duodenal ulcer may be subjected to gastro-enterostomy plus subphrenic vagotomy.

With reference to a question as to the harmful effects of postoperative achlorhydria, we have a large series of patients followed up for fifteen years who had an achlorhydria after partial gastrectomy. Many of these had a true achlorhydria, they have not shown any anemia or other harmful effects from the achlorhydria.

Professor Babkin has asked me to explain why it is that we get achlorhydria and no recurrences after gastric ulcer, whereas we get acid and recurrences after duodenal ulcer in some cases. We have found in gastric ulcer that the pre-operative acidity is quite low. Post-operatively there is invariably an achlorhydria. It is true achlorhydria

as proved by histamine and neutral red. Since it is a true achlorhydria, there are two possibilities; one that the secretory tissue is almost completely excised, and the other a gastritis is present which inhibits the glands. It is possible that the two together are responsible for the achlorhydria.

In gastric ulcer where the lesion is at the lesser curvature angle a larger resection is forced on the operator than in duodenal ulcer.

The final point, made by Dr. Sullivan, seems to concern itself with the question of terminology. We believe one should differentiate sharply between the ultimate cause of peptic ulcer and the mechanism by which it is produced. At present I think the ultimate cause is one of three possibilities, psychogenic disease, ductless gland disease, and possibly an inflammatory disease, gastritis or duodenitis, leading to ulcer. Concerning the mechanism, I believe all observers will agree with me in saying that three factors are of vital importance there, viz; the irritant, the acid and the tissue susceptibility factor. The second, or acid factor, seems of central importance in the ulcer problem.

The Development and Healing of Gastric Ulcer—A Clinical, Gastroscopic, and Roentgenologic Study

By

WALTER LINCOLN PALMER, M.D., RUDOLF SCHINDLER, M.D.

and

FREDERIC E. TEMPLETON, M.D.

THE essence of the ulcer problem is to be found in two closely related processes: the pathogenesis of the lesion and the mechanism of healing. For the past several years we have been engaged in a careful study of gastric ulcer, focussing our attention upon these two aspects. It is apparent that the only objective methods available for the protracted observation of ulcer are those of roentgenology and gastroscopy. Frequent use of both of these methods has been made in the patients under observation.

A year ago a preliminary report (1) was published in which it was pointed out that X-ray and gastroscopy are complementary rather than competitive methods of examination. We have frequently noted that small ulcers, visible gastroscopically, may not be seen by X-ray and, on the other hand, that ulcers identified roentgenologically may not be found gastroscopically. In this latter group the lesions usually occur in the so-called gastroscopic "blind areas," particularly along the lesser curvature of the antrum and on the posterior wall of the body of the stomach near the lesser curvature. The importance of checking gastroscopically a negative X-ray examination, or vice versa, is comparable to that of checking the fluoroscopic examination with films.

A careful study of the appended case reports will reveal the extent of these discrepancies and will also show that occasionally the same ulcer may be seen at one gastroscopic or roentgenologic examination and not be seen at another time even with the same method, although the lesion is known to be still present.

This article is based primarily upon fourteen cases, chosen to illustrate certain definite points. A brief summary of these cases and protocols of the gastroscopic and roentgenologic examinations in each are given. The important points to be brought out are: (1) that an acute ulcer may appear and disappear quickly; (2) that an ulcer may increase in size; (3) that after complete healing has taken place an ulcer may recur in approximately the same location or in an adjacent area; (4) that symptoms may be entirely absent; (5) that the mucosal changes may vary from a perfectly normal mucosa to superficial, atrophic, or hypertrophic gastritis, with or without hemorrhages or pigment spots; (6) that the rate of healing varies greatly in different cases; (7) that adequate nutrition, acid neutralization, and avoidance of concurrent infection are important in promoting healing; and (8) that those cases exhibiting delayed healing are often accompanied by interference with gastric emptying and usually with narrowing of the antrum.

PATHOGENESIS

Theories of ulcer formation have been generally divided into the chemical, infarctive, traumatic, and inflammatory (2). Günstzberg (3) in 1852 related gastric ulcer to the effect of the gastric juice on the mucous membrane. Subsequently Rokitsansky (4) and R. Virchow (5) postulated the concept of organic or functional closure of the vessel with resultant hemorrhagic or anemic necrosis and digestion of the necrotic tissue by the gastric juice. These views were supported by Hauser (6), von Bergmann (7), and many others, and have been the prevailing theories of ulcer

Fig. 1 (Case 1). Three of the six ulcers found on January 25, 1935, are well shown. Note their complete disappearance by February 25. The large ulcer adjacent to the gastro-enterostomy stoma, found January 6, 1937, was found in a control examination, produced no symptoms, and subsequently was found to have healed completely.

formation. There is evidence that abnormal trauma may play a role in the development of ulcer but there is every reason to think that this is a rare occurrence. The fourth theory, namely the inflammatory basis of

ulcer, has in recent years been most ardently supported by Moszkowicz (8), Konjetzny, Puhl (9) and others. The evidence offered is chiefly pathologic. This point of view is well stated by Konjetzny in the following paragraph:

"Es ist gleich ein Streitpunkt vorwegzunehmen, der sich darauf bezieht, ob die drei Formen der geschwürigen Bildung im Magen und Duodenum (Erosion, akutes und chronisches Ulcus) ineinander übergehen oder ob das typische Ulcus von vornherein in seiner Form vorausbestimmt ist, wie es vor werden: *das typische Ulcus des Magens und des Duodenum entsteht aus einer Erosion, der erste Vorgang der Geschwürsbildung spielt sich also in der Schleimhaut ab*" (10)."

It is important to point out that this concept resembles the chemical theory in that it postulates a progressive penetrating process.

There is abundant experimental evidence that the ulcer process begins in the mucosa and penetrates into the submucosa, and muscularis. The clinical behavior of peptic ulcer is, of course, in accord with this view for it is well recognized that a chronic ulcer may undergo massive hemorrhage or acute perforation—a process presumably due to extension and penetration of the lesion. Relatively few direct, objective, clinical observations have been reported to substantiate this assumption. Berg (11) has published two roentgenograms of a gastric ulcer taken at an interval of one and a half years definitely showing an increase in size. Ten days after the last examination the ulcer perforated. Buckstein (12) refers to the "gradual increase in the size of a gastric niche coincidental with aggravation of the clinical symptoms. Forssell (13)

*Italian ours.

CASE 1

H. M., Female, Age 33, Unit No. 120421, X-ray No. 37762

The patient had had gnawing epigastric distress from 1928 to 1930 when a posterior gastro-enterostomy was performed. Distress recurred in 1934. The patient entered the hospital January 21, 1935, and was discharged symptom-free February 27, 1935. During 1936 there was no definite distress even at the time of the gastroscopic demonstration of ulcer in November, 1936, and January, 1937. The distress recurred in July, 1937, but no studies were made (patient did not report). Maximum free acidity (control aspiration) 32. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
1-25-35	Two gastric ulcers just above the angle, opposite the gastro-enterostomy stoma; upper one, 3 mm. wide, 2 mm. deep; lower one, 8 mm. wide, 5 mm. deep.	1-25-35	Six shallow ulcers along lesser curvature, four in a line and two on the anterior wall. The uppermost ulcer was the largest, appearing to be about 4 cm. long.	Edge of ulcers hyperemic, mucosa otherwise normal; gastro-enterostomy with pylorus-like activity.
2-25-35	No ulcer seen.	2-25-35	Ulcers healed.	One small hemorrhagic erosion in anterior wall; large pigment spot, lesser curvature; slight superficial gastritis high on lesser curvature and about the gastro-enterostomy stoma.
		5-10-35	No ulcer.	Two small mucosal hemorrhages, lesser curvature.
		7-18-35	No ulcer.	Normal.
		3-25-36	No ulcer.	Two pigment spots beneath cardia.
		11-11-36	Two shallow ulcers between stoma and pylorus.	Normal.
1-6-37	Stoma ulcer?	1-6-37	Large marginal ulcer in the gastric mucosa adjacent to the gastro-enterostomy stoma.	Mucosal hemorrhages of lesser curvature—one hemorrhagic erosion of lesser curvature.
		4-28-37	No ulcer seen.	Chronic hypertrophic gastritis of lesser curvature above the angulus.
4-28-37	No ulcer.			

Fig. 2 (Case 3). Note the definite variation in the size of the lesion from time to time.

Fig. 3 (Case 4). Note the definite increase in the size of the lesion between April 26 and October 12 and its subsequent decrease in size to November 24 and February 18, the increase apparent November 4 and the decrease again by April 5, 1938. The narrow antrum is evident in all of the views.

implies such a process in the clause, "If the disease process wins the upper hand and necrosis and infiltration proceed*..." Cole's conception (14), on the other hand, is that "the pathogenesis of ulcer is similar to that of a boil. The ulcer begins as an area of inflammation within the wall of the gut, and as this goes on

CASE 2

L. H., Female, Age 24, Unit No. 123238, X-ray No. 38626

The patient entered the hospital March 18, 1935, because of an epigastric "pressure sensation" of one year's duration, intermittent, relieved by vomiting. She was discharged symptom-free March 30, 1935, on "Sippy" management. April 11th she was readmitted because of the passage of a tarry stool. The stools soon became negative for occult blood on ulcer management and the patient was discharged May 13, 1935. Indefinite abdominal distress has continued to date (December 22, 1937), not of the ulcer type, and induced apparently by fatigue and emotional disturbances. Maximum free acidity (Ewald) 34. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
3-5-35	No ulcer	3-8-35	Red bleeding shallow ulcer, upper lesser curvature.	Normal.
3-20-35	No ulcer	3-23-35	No ulcer seen.	Hypertrophic gastritis at the site of the ulcer.
4-26-35	No ulcer	4-24-35	Marked gray-yellow ulcer in the area of hypertrophic gastritis.	
		5-10-35	Shallow ulcer.	No gastritis.
		7-16-35	No ulcer.	No gastritis; small hemorrhages in the mucosa in the fornix.
		3-24-36	No ulcer.	No gastritis; streak-like hemorrhage in region of old ulcer.

to liquefaction necrosis, it breaks into the lumen of the gut, and then the necrotic core is extruded into the lumen or it may also simultaneously break into the peritoneum." Extension of a lesion once formed is not compatible with this concept.

Gutzeit and Teitge (15) have well described the breakdown of an "Ulcusrezidiv" with recurrent ulcer formation as observed gastroscopically:

"Jede Ulcushheilung passiert dieses Stadium der ungenügend gefestigten Narbe. Hierbei sind die Ulcusränder zwar schon zusammengezogen. Zwischen ihnen aber befindet sich ein feiner Spalt, aus dem ein heller Fibrinstreifen hervorsieht. In dieser Phase sind die Beschwerden meist abgeklungen, und röntgenologisch ist eine Nische nicht mehr darstellbar. Das Ulcus scheint also nach dem klinischen und röntgenologischen Befund geheilt zu sein. Bei der gastroscopischen Kontrolle wird erst der verhängnisvolle Irrtum solcher Annahme aufgezeigt. Das Ulcusrezidiv des ungeheilten Ulcus kann nur bei rechtzeitiger Kenntnis des

oberflächenanatomischen Befundes verhütet werden. Denn gestattet man einem solchen Kranken eine Lockerung seiner diätetischen Lebensweise, dann brechen die eben verklebten Ulcusränder wieder auseinander, und der offene Geschwürskrater tritt wieder zutage,* ein Ereignis, das eine mehrwöchige Ulcusbehandlung um ihre Früchte zu bringen vermag. Nicht

CASE 3

R. M., Female, Age 56, Unit No. 145262, X-ray No. 45939

The patient entered the hospital February 7, 1936, because of periodic epigastric distress of three years' duration. She was discharged on ulcer management February 20, 1936, but she did not follow the program carefully. Distress recurred in August, the crater recurred, and the patient was readmitted October 22, 1936. The pain disappeared, the crater decreased in size, and the patient was discharged November 11, 1936. In January, 1937, the pain recurred and the crater had enlarged. The patient was instructed to remain in bed at home on strict Sippy management for one month and was finally induced to continue the strict program for a year. Neither the pain nor the ulcer has reappeared. Maximum free acidity (histamine) 100. Gastroscopy was not performed (resistance at the cardia), but the roentgenologic findings are tabulated:

X-RAY		GASTROSCOPY	
		Ulcer	Mucosa
2-11-36	Gastric ulcer beneath cardia, 12 mm. wide, 6 mm. deep.	(Gastroscopy not performed because of resistance at the cardia).	
3-14-36	Scar, but no crater (pain gone).		
10-1-36	Crater in same place, 19 mm. wide, 13 mm. deep (recurrent distress).		
11-10-36	6 mm. wide, 5 mm. deep (pain gone).		
2-9-37	15 mm. wide, 9 mm. deep (recurrent pain).		
3-9-37	No ulcer (pain gone).		
6-8-37	No ulcer (pain gone).		
8-10-37	No ulcer (pain gone).		
10-19-37	No ulcer (pain gone).		
12-28-37	No ulcer (pain gone).		
3-31-38	No ulcer (pain gone).		

eine Lockerung, sondern eine gewissenhafte Weiterführung der diätetischen Behandlung kann solchen Schaden wirksam verhüten."

The sudden appearance of an acute ulcer and its subsequent rapid healing has been noted rather frequently in our studies. An excellent illustration is that of Case 1 (Fig. 1) in which six discrete ulcers along the lesser curvature were observed gastroscopically on January 25, 1935. A month later they had disappeared, leaving no trace behind. A similar process occurred in Case 2, the protocol only being given. These small ulcers were scarcely visible roentgenologically.

Definite evidence has been obtained in several of the cases under observation that small ulcers may increase in size (Cases 3 to 11 inclusive). In Case 3,

*Italics ours.

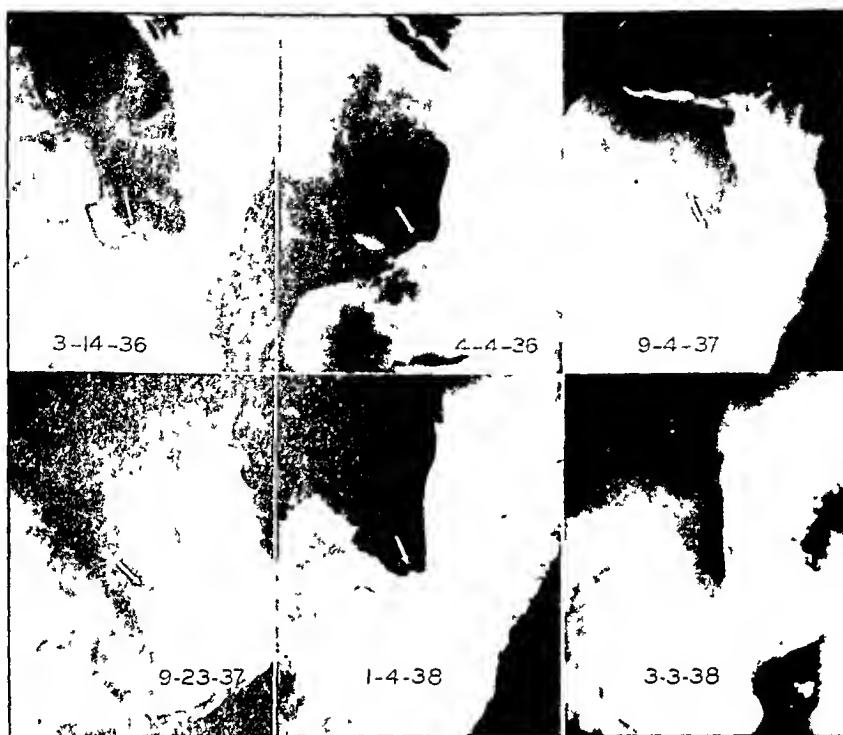

Fig. 4 (Case 5). The variation in the size of the ulcer is apparent. The constant narrowing of the antrum is well shown in four of the six views.

roentgenologic evidence only is available but this is definite as may be seen from Fig. 2. In Case 4, the most definite evidence of increase in size is the roentgenologic in which the marked progression of the lesion is unmistakable if one compares the initial film, taken 4-21-36, with the later one, taken 10-12-36, Fig. 3. In Case 5, the variations in size observed roentgenologically may be easily seen in Fig. 4. Similar changes were seen gastroscopically. In Case 6, the variations are clearly shown roentgenologically in Fig. 5 but are perhaps more difficult to follow in the protocol of the gastroscopic examinations. It is significant in this connection that estimation of the size of the lesion is more difficult gastroscopically than it is roentgenologically. In Case 7, the protocol shows clearly the changes in the size of the lesion as observed both roentgenologically and gastroscopically. In Case 8, the X-ray examinations were definite but the gastroscopic evidence was even more conclusive, Fig. 6. In this instance the localization of the lesion was facilitated and made more exact gastroscopically by the constant finding at the site of the ulcer of an unusual pattern of the rugae. The decrease in the size of the ulcer from April 4 to April 14 and its reappearance at the same site by September 1 is unmistakable. In Fig. 7, the X-ray evidence of similar alterations in the prepyloric ulcer of Case 9 is clear. Case 10 is quite similar, the lesion decreasing from November 19, 1934, to February 16, 1935, increasing by December 14, disappearing by April 4, 1936, and continuing absent in October, 1936, and February, 1938, during which time the patient remained well clinically, Fig. 8. The ulcers in these two cases

were in a gastroscopic "blind area" but nevertheless in the second, Case 10, the lesion was visible in three of the five gastroscopic examinations made. In Case 11, the recurrent lesion, repeatedly seen roentgenologically in April, May, June and September of 1937, increased in size in October and November (Fig. 9). It is interesting to note that this definite ulcer was not seen gastroscopically until November when it was described as "gigantic." Fig. 10 is included to show a splendid illustration of the same process in a duodenal ulcer (Protocol not given). The progressive enlargement of the crater is unmistakable in the first four views and its subsequent decrease in the following views is equally clear.

In this series the extension of the lesion usually occurred without any symptoms. This is probably due to the fact that the patients were on a more or less modified Sippy program, the modification being inversely proportional to the willingness and ability of the patient to carry out the program. Generally speaking, and with certain exceptions to be noted later, the greater the modification, the greater was the likelihood of increase rather than decrease in the size of the lesion or of recurrence if the ulcer had healed.

In Case 12, the complete healing of the ulcer was shown by repeated roentgenologic and gastroscopic examinations. The ulcer reappeared at the same site, just above the angulus, six months later but apparently healed promptly. Eight months later another lesion appeared slightly lower on the lesser curvature (Fig. 11). This lesion was just below the angulus whereas the two previous lesions were just above it.

Fig. 12 shows the disappearance of the first ulcer located on the angulus and the subsequent formation of a new ulcer in the antrum as seen gastroscopically. In this instance we have to do, then, with recurrence at a definitely different site.

The protocols of Cases 13 and 14 illustrate healing and recurrence at approximately the same site. These observations are quite in accord with the following statement made by Schindler (16) in 1937: "Frequently the new ulcer occurs in exactly the same place as the original lesion; sometimes it is in immediate proximity to the original site, and sometimes in a different place." The observations are also consistent with the known tendency of ulcers to recur after gastroenterostomy. A similar phenomenon is observed in the occasional development of gastric ulcer in patients known previously to have had duodenal ulcer.

It is noteworthy that acute ulcers often were not accompanied by symptoms as for instance in Case 1, in which the acute ulcers seen gastroscopically in November, 1936, and January, 1937, were accidental findings only. Similarly increase in size was frequently noted

without distress or other symptomatic evidence of progression. (See Cases 6 and 11 particularly). It seems to us clear that this clinical evidence is in complete accord with the view that ulcer formation is the result of an "erosive" rather than infarctive process and that chronic ulcer develops from an acute ulcer. The cause of the initial erosion is not touched upon here. Erosions are roentgenologically invisible. Gastroscopic evidence of the relationship between erosions and ulcer is perhaps a matter of definition. Both Schindler and Gutzeit agree, however, that an ulcer may develop from the so-called "ulcusrezidiv."

This question leads at once to a consideration of the relationship between ulcer and the so-called mucosal changes, or, more specifically, gastritis. Pathologically, Konjetzny finds gastritis constantly present in ulcer, the gastritis being of the so-called "antral" type, involving particularly the lesser curvature of the stomach, the antrum, and the first portion of the duodenum (Puhl (9)). Gastroscopically the mucosal changes in our cases varied greatly. In some the mucosa was normal; in others hemorrhages, pigment

CASE 4

A. M., Male, Age 75, Unit No. 149893, X-ray No. 47526

The patient entered the hospital April 20, 1936, because of occasional attacks of vomiting of five years' duration. There had been no pain. A gastric ulcer was demonstrated roentgenologically. Further hospitalization for treatment was advised and refused. On October 10, 1936, the patient was readmitted because of massive, almost fatal, hematemesis and melena. The patient was discharged symptom-free December 11, 1936, but the ulcer has not completely healed to date (April 5, 1938). Deep radiation therapy was administered for ten days in daily doses of approximately 300 r (measured in air), alternately through anterior and posterior portals directed at the upper two-thirds of the stomach, the total dosage being 2930 r, the last treatment being given October 13, 1937. Maximum free acidity (histamine) 58. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY	
		Ulcer	Mucosa
4-21-36	Ulcer just above the incisura angularis, 6 mm. wide, 3 mm. deep. Pyloric narrowing; 24-hour retention.		
10-12-36	Ulcer in same region, 25 mm. wide, 12 mm. deep.		
11-24-36	15 mm. dia., 16 mm. deep.		
12-29-36	10 mm. dia., 7 mm. deep.	12-10-36 Healing ulcer on angulus.	Two small mucosal hemorrhages.
1-20-37	7 mm. dia., 4 mm. deep.	1-20-37 Large benign ulcer above angulus.	One hemorrhagic erosion of posterior wall in mid-part of body.
2-18-37	5 mm. dia., 4 mm. deep.	2-24-37 Ulcer much smaller; converging folds.	Hypertrophic gastritis about the ulcer.
3-18-37	8 mm. dia., 12 mm. deep.	3-24-37 Ulcer crater invisible; converging folds at the angulus.	Nodular hypertrophic gastritis of greater curvature of antrum and of posterior wall.
5-23-37	3 mm. dia., 2 mm. deep.		
6-23-37	No ulcer seen.		
8-20-37	No ulcer seen.		
9-27-37	3 mm. dia., 3 mm. deep.	9-29-37 Spasm; ulcer area not visible.	
11-4-37	10 mm. dia., 5 mm. deep.		
		12-1-37 Ulcer at angulus.	Atrophic gastritis of antrum and superficial gastritis of body.
12-25-37	3 mm. dia., 2 mm. deep.	1-6-38 No ulcer seen.	Slight superficial gastritis of antrum and body.
2-10-38	3 mm. dia., 2 mm. deep.	2-16-38 Remnant of former ulcer, 1 to 2 mm.	
		3-16-38 No ulcer seen.	Chronic superficial gastritis.
4-5-38	2 mm. dia., 1 mm. deep.		

Narrowing of the smooth and pliable antrum was constantly noted throughout each examination but the narrowing has become less marked in the more recent examinations.

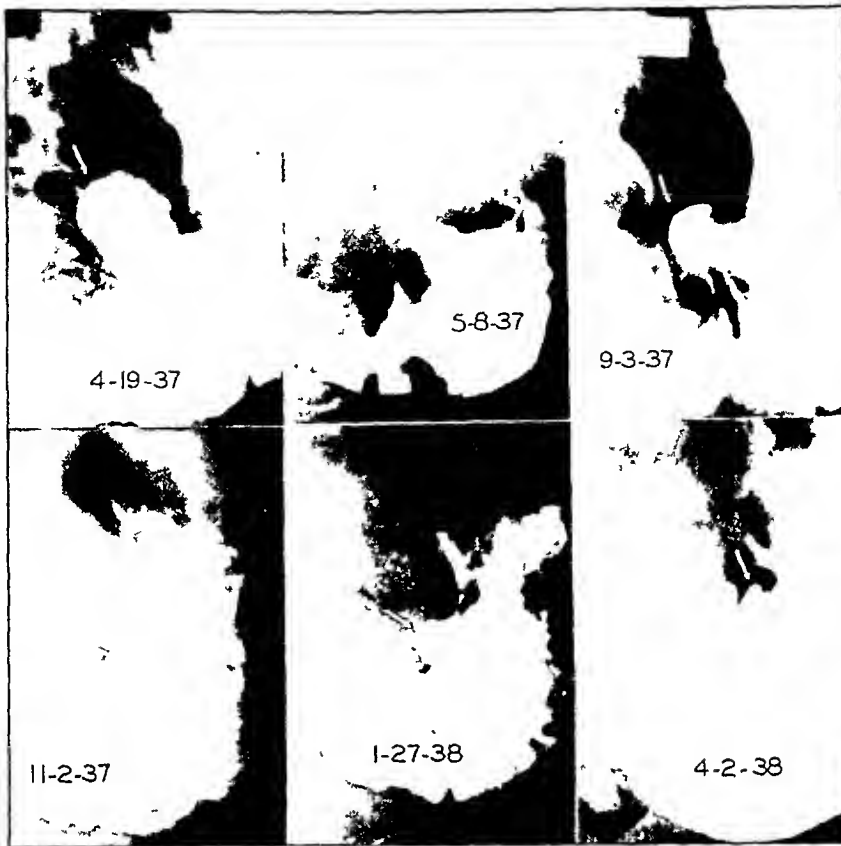

Fig. 5 (Case 6). Note the decrease in the size of the crater from April 19 to May 8, the subsequent increase by September 3, the decrease again to November 2, the definite enlargement again by January 27, and once more the decrease to April 2.

Fig. 6 (Case 8). Note the definite decrease in the size of the ulcer from April 4, 1936, to April 14, 1936, the ease of localization by means of the characteristic pattern of the folds, the increase in the size of the ulcer from April 14, 1937, to September 1, 1937, and subsequent healing by February 9, 1938. The mucosa is essentially normal.

spots, and hemorrhagic erosions were seen; superficial gastritis was not infrequent and hypertrophic gastritis of all grades of severity was a common finding. Not only did the changes vary greatly from patient to patient but also in the same patient from time to time, as may be noted by examining the protocols. In Case 7, for instance, the mucosal change varied from a marked hypertrophic gastritis to normal mucosa with one pigment spot and numerous small hemorrhagic areas, to a hypertrophic gastritis, then to a normal mucosa, then a hypertrophic gastritis in varying grades of severity and, most recently, a chronic superficial gastritis.

HEALING PROCESS

Roentgenologically, it has been known for years that even though the niche of a penetrating gastric ulcer is quite large, it may disappear quickly under treatment. This does not prove that the healing is complete for the ulcer may persist after the niche has disappeared. Schindler, however, observed gastroscopically the disappearance of an ulcer and epithelization in five and one-half weeks. He has subsequently observed lesions in which the healing process was much more delayed. Rapid healing has already been mentioned as having been seen in several of our patients, particularly Cases 1, 2, 12, 13 and 14. In several, however, healing has been very, very slow. Thus, in Case 6, Fig. 5, it is not complete at the end of a year,

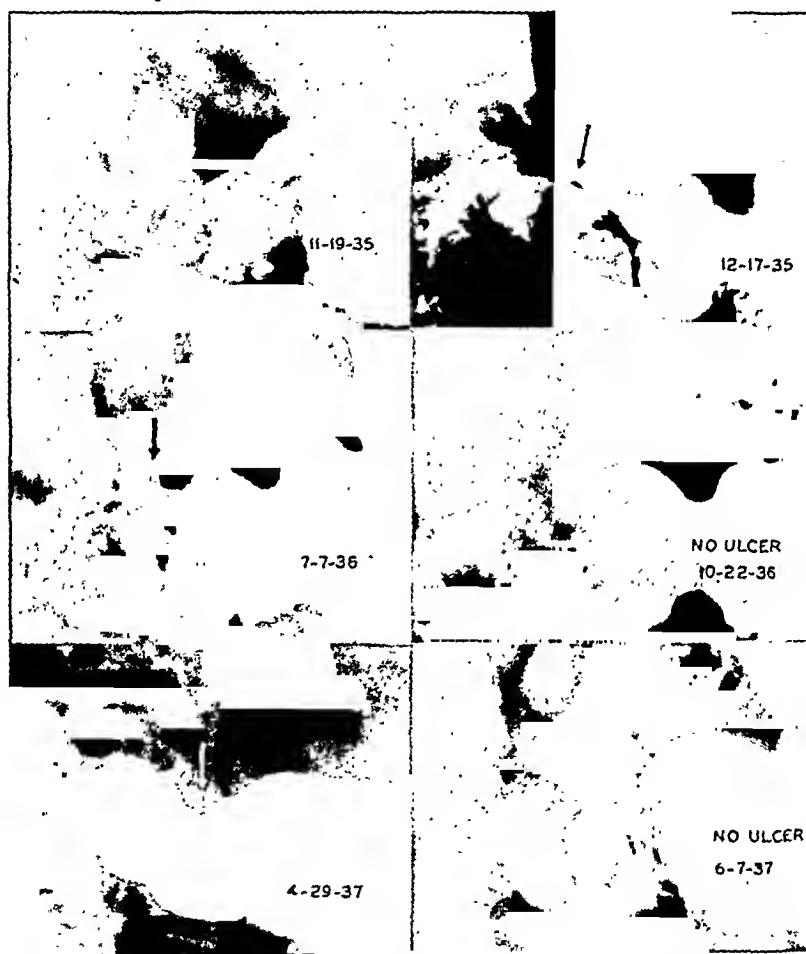

Fig. 7 (Case 9). Note definite variation in size of prepyloric ulcer in the first three views, its disappearance in the fourth, and its recurrence in the fifth.

and in Cases 4 and 5, Fig. 3 and 4, it is not yet complete at the end of two years. In studying the various cases in an attempt to discover the cause of the slow healing or of the recurrences, there seems to be reason to attribute the difficulty in many instances to the failure of the patient to carry out the program of rest, high-calorie diet, and acid neutralization. This was specifically true in Cases 3, 7, 8, 9 and 10. When sufficiently impressed with the importance of the regime or when hospitalized, all of these patients would make excellent progress symptomatically and the ulcer would improve objectively. Complete healing apparently occurred in Cases 3, 9 and 10, when they finally became adequately impressed with the necessity for continuous, vigorous treatment and, in Case 8, when it was made economically possible for the patient to follow the program. Concurrent infection did not seem to play a *specific* role in either recurrence or exacerbation but, on the other hand, it was frequently observed to have a deleterious effect in the same manner as overwork, worry, fatigue, and the failure to follow the prescribed regimen.

In several cases, however, healing occurred very

slowly even though the management was faithfully followed (Cases 4, 5, 6 and 7). It is noteworthy that in all of these gastric emptying was slow and that, except in Case 6, the antrum of the stomach was persistently narrow although pliable and smooth as in Figs. 3 and 4. This narrowing of the antrum has been known for many years, having been described by Carmen (17) and attributed to reflex spasm. Golden (18) has recently called attention to this condition again and suggests that it is due to an "inflammatory reaction of the gastric wall. . . It seems possible that the mechanism of the antral spasm is an effect of edema and inflammation on the ganglions." The subject was discussed in detail by Schindler and Templeton (19) last year. In the series of cases under consideration the gastroscopic examination did not disclose a satisfactory explanation of the narrowing of the antrum. No more evidence of gastritis was found, on the whole, in the group with antral narrowing than in the group without this condition. Gastroscopy, of course, visualizes only the mucosa and the finding of a normal mucosa does not disprove the possibility that inflammation may be present in the muscularis, as we have

CASE 5

T. L., Male, Age 54, Unit No. 147849, X-ray No. 46658

The patient gave an indefinite story of intermittent epigastric distress of at least two, and perhaps seven, years' duration. He entered the hospital March 12, 1936, and was discharged on treatment April 11, 1936. He did not follow the treatment carefully and in May, 1937, the distress recurred. The patient then resumed and fairly well maintained the prescribed program. Deep radiation therapy was administered for ten days in daily doses of approximately 300 r (measured in air), alternately through anterior and posterior portals directed at the upper two-thirds of the stomach, the total dosage being 2930 r, the last treatment being given September 18, 1937. Distress has not recurred to date (April 23, 1938). The ulcer has varied in size from time to time and is not yet healed. Maximum free acidity (histamine) 130. The roentgenologic and gastroscopic findings are tabulated:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
3-14-36	Gastric ulcer at angle, 10 mm. wide, 15 mm. deep; radiating mucosal folds, duodenal deformity, no crater.			
3-20-36	9 mm. wide, 7 mm. deep	3-18-36	Benign crater-like ulcer in the angulus.	Pallor of mucosa—no gastritis.
4-4-36	5 mm. wide, 2 mm. deep.	4-2-36	Healing benign ulcer at angulus.	No gastritis; large fresh hemorrhage high on posterior wall, bleeding into cavity of stomach.
4-10-36	4 mm. wide, 1.5 mm. deep.	4-17-36	Healing gastric ulcer at angulus, shaped like a five-pointed star.	Marked superficial gastritis, lesser curvature.
5-27-37	Ulcer, 8 mm. wide.			
5-23-37	5 mm. wide.	6-23-37	Normal stomach.	
9-4-37	3 mm. wide, 2 mm. deep.	9-1-37	No ulcer.	Hypertrophic gastritis, antrum and posterior wall.
9-23-37	8 mm. wide, 4 mm. deep.	9-21-37	Healing ulcer at angle.	Slight superficial gastritis—two mucosal hemorrhages.
10-5-37	9 mm. wide, 7 mm. deep.			
11-3-37	Shallow ulcer.			
12-6-37	4 mm. wide, 2 mm. deep			
1-4-38	13 mm. wide, 2 mm. deep.	2-9-38	Ulcer 15 mm. wide.	Superficial gastritis.
3-3-38	Ulcer gone.			
3-30-38	Shallow ulcer seen at the angle, 3 mm. wide, 2 mm. deep.	3-30-38	Two benign ulcers of the lesser curvature of the angulus and the antrum.	No inflammation.

In each and every roentgenologic examination the antrum was described as narrow but pliable.

indeed observed pathologically in one case. It seems unlikely that spasm of the antrum would be as constant and persistent as the antral narrowing observed in these cases has been. Hypertrophy of the pyloric muscle, as described by many workers since Cruveilhier (20), may also have been present and may have been the sole cause of the delayed emptying in Case 6 (Fig. 5). Differentiation is difficult clinically between hypertrophy of the pyloric muscle, spasm of the muscle, and failure of the muscle to relax, the so-called achalasia of the pylorus (Hurst (21)). Regard-

less of the mechanism involved, gastric retention was definitely present in this group of cases and, in our opinion, played a very significant role in retarding the healing of the ulcer.

CONCLUSIONS

1. The clinical, gastrosopic, and roentgenologic evidence support the concept of ulcer as a penetrative process beginning in the mucosa and invading the deeper layers of the gastric wall.
2. The healing process, under favorable conditions,

CASE 6

W. F., Male, Age 59, Unit No. 173277, X-ray No. 56016

The patient entered the hospital April 18, 1937, because of epigastric pain of the ulcer type of only five and a half months' duration. It had been accompanied by anorexia, weakness, vomiting, constipation, and a thirty-five-pound loss of weight. On ulcer management the pain subsided promptly, the stools became free of occult blood, the patient gained weight, and the ulcer decreased in size. The patient was discharged May 26, 1937, and seen frequently in the out-patient department. Deep radiation therapy was administered for nine days in daily doses of approximately 300 r (measured in air), alternately through anterior and posterior portals directed at the upper two-thirds of the stomach, the total dosage being 2651 r, the last treatment being given August 9, 1937. He continued to feel well but because of objective evidence of increase in the size of the ulcer, he was readmitted to the hospital September 1, 1937. The ulcer again decreased in size, and so the patient was discharged October 6, 1937. He continued in excellent health and strength but the lesion increased in size upon his return to work. He was therefore readmitted January 29, 1938, and has remained in the hospital to date (April 25, 1938). The lesion is decreasing slowly in size. Occult blood is consistently absent from the stool. The patient looks and feels well and is gaining in weight (total gain to date, 7.4 kg.). Maximum free acidity (histamine) 60. The roentgenologic and gastrosopic data are shown in the following summary:

X-RAY			GASTROSCOPY	
			Ulcer	Mucosa
4-18-37	Ulcer of lesser curvature 4 cm wide.	4-25-37	Benign ulcer.	Atrophic hemorrhagic gastritis of fundus (unusual in benign ulcer).
5-8-37	16 mm. wide.	5-12-37	Ulcer smaller, radiating folds.	
		5-19-37	Ulcer 50% smaller than last time; converging folds.	Chronic superficial gastritis about ulcer.
5-23-37	15 mm. wide.	6-2-37	Healing ulcer.	Chronic hypertrophic gastritis about ulcer.
6-20-37	17 mm. wide.	July, 1937	Healing chronic benign ulcer with five radiating folds.	Normal.
		8-11-37	Healing ulcer, shallower.	Normal.
9-3-37	23 mm. wide.	9-1-37	Ulcer; elevation in floor—food retention or carcinoma?	On greater curvature opposite.
		9-10-37	Ulcer, benign—elevation seen in last examination apparently food.	Normal.
9-21-37	20 mm. wide.	9-24-37	Ulcer shallower but at least 2 or 3 cm. wide; four converging folds.	Normal.
10-5-37	18 mm. wide.	10-1-37	Ulcer shallower—small red polyp-like protuberance in sharp anterior edge—carcinoma?	Normal.
		10-11-37	Ulcer healing, protuberance present.	Normal.
10-15-37	13 mm. wide.	10-20-37	Ulcer healing, shallower—edges irregular from ingrowing islands of mucosa.	One hemorrhage.
11-2-37	13 mm. wide.			
12-21-37	16 mm. wide.	12-16-37	Large shallow ulcer, not crater-like but very irregular; former islands of mucosa gone.	Normal.
1-27-38	17 mm. wide.	1-29-38	Ulcer about 1.5 cm. wide.	Swollen mucosa about ulcer.
2-12-38	15 mm. wide.	2-11-38	Healing ulcer.	Surrounding gastritis.
		2-18-38	Large, shallow, irregular ulcer with ragged edges surrounded by reddened halo.	Inflammation about ulcer.
3-12-38	16 mm. wide.	3-7-38	Ulcer now seen beyond the rugae; ulcer seemed to be divided into two portions by a ridge of mucosa.	Mucosa of angle swollen and thickened, that of entire stomach reddened and mottled—due to food retention?
4-2-38	9 mm. wide.	3-31-38	Ulcer deeper and more regular than at last examination.	Slight inflammation about ulcer.
4-21-38	9 mm. wide.			

Delayed gastric emptying was present throughout as evidenced by the fluid retention noted at the beginning of each examination and, in the later examinations particularly, by the difficulty in getting the barium to leave the stomach. There was no narrowing of the antrum. The pylorus appeared to be in spasm, or at least it failed to open.

Fig. 8 (Case 10). Note the decrease in size from November 19, 1934, to February 16, 1935, the increase by December 14, and the disappearance by April 4, 1936. The lesion did not recur subsequently judging from the examinations of October 24, 1936, and February 19, 1938, and the continued lack of symptoms.

proceeds rapidly and leads to "restitutio ad integrum" so complete that the scar is scarcely visible gastroscopically.

3. Failure of the lesion to heal may be due to the failure or inability of the patient to carry out an adequate regimen of rest, acid neutralization, and diet, or to failure of the stomach to empty properly.

4. Delayed gastric emptying in gastric ulcer is frequently associated with and probably attributable to organic or physiologic narrowing of the antrum, failure of the pylorus to open, or both. The mechanism involved is not yet entirely clear.

Note (Sept. 20, 1938): The patient, W. F. of Case 6, was submitted to operation by Dr. Alexander Brunschwig on June 25, 1938. A hypertrophy of the pylorus was found, accounting presumably for the continued gastric retention. The lesser curvature of the stomach was adherent to the left lobe of the liver by a fibrotic cord. A partial gastrectomy was performed, three-fifths of the stomach being removed. A small ulcer, measuring about 5 mm. in diameter, was found in the mucosa near the site of the adhesion of the lesser curvature to the liver. Convalescence has been uneventful. The gastric ulcer of Case 11, patient W. R., recurred again in June, symptoms having been present for one month. Healing is not yet complete, as evidenced by repeated gastroscopic and roentgenologic observations.

DISCUSSION

DR. MARTIN E. REHFUSS (Philadelphia, Pa.): Mr. Chairman, Ladies and Gentlemen: I don't believe I have ever seen or heard a much better paper. I am very much impressed not only with the pictures but also with the

excellent X-ray findings that are so beautifully visualized that no one could possibly miss them.

When Dr. Boles asked me to discuss this paper, it took me back to the question of the diagnosis of gastric ulcer. I have always maintained that the only diagnosis that counted was the visual diagnosis by X-ray or by gastro-scope. It was my good fortune to spend six months with Dr. Haudeck, in Vienna, a little over twenty-six years ago,

and he was making the diagnosis of gastric ulcer by noticing the first material that enters the stomach (using blackboard). I can well recall as the material went down the stomach, Dr. Haudeck would point out the necessity for examination with the first few mouthfuls of opaque material in such fashion you would see the little tack-like crater.

A little later on when we became very much more

CASE 7
W. G., Male, Age 46, Unit No. 144032, X-ray No. 45433

The patient gave a history of periodic epigastric pain of fourteen years' duration. "Ulcer" was said to have been found by X-ray in 1922 and again in 1928. Under ambulatory management the patient became symptom-free and the ulcer healed. A "modified Sippy" program was continued, but the pain and the crater recurred in March and April, 1937. The pain subsided promptly upon the resumption of a more strict program, but the crater diminished slowly, as seen in the table to follow. Deep radiation therapy was administered for ten days in daily doses of approximately 300 r (measured in air), alternately through anterior and posterior portals directed at the upper two-thirds of the stomach, the total dosage being 2930 r, the last treatment being given September 22, 1937. Maximum free acidity (histamine) 115. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
1-10-36	Gastric ulcer just above angle; 7 mm. wide, 5 mm. deep; irregular antrum — gastritis?	1-20-36	Ulcer at angulus; curious pouch formation at anterior margin of angulus — perigastric adhesion?	Marked hypertrophic gastritis of the body, not of the antrum.
		2-14-36	Ulcer smaller; pouch the same.	Gastritis improved.
3-11-36	3 mm. wide, 1 mm. deep; irregular antrum, retained fluid.	3-14-36	Ulcer decreased to about one-fourth its previous size.	Marked gastritis still present.
		4-18-36	Ulcer almost healed; pouch unchanged.	Hypertrophic gastritis still present.
		6-16-36	Ulcer at angulus 5 mm. in diameter.	No significant gastritis; one pigment spot and numerous small mucosal hemorrhages.
7-2-36	5 mm. wide, 2 mm. deep; antral narrowing.	7-22-36	Very small ulcer; 3 mm. in diameter; same pouching.	Hypertrophic gastritis of body.
8-12-36	No ulcer.	8-12-36	Scar; 3 converging folds.	Mucosa normal.
4-13-37	Ulcer just above the incisura angularis; 3 mm. wide, 4 mm. deep.	4-14-37	Round, not very deep ulcer just above the angulus, 5 to 6 mm. in diameter.	Hypertrophic gastritis of anterior wall just above the angulus.
5-11-37	4 mm. wide, 2 mm. deep.	5-12-37	Narrow antrum; ulcer almost healed.	Chronic hypertrophic gastritis of anterior wall, high on lesser curvature.
5-25-37	3 mm. wide, 2 mm. deep.	6-2-37	No ulcer.	Severe hypertrophic gastritis of lesser curvature and antrum.
6-4-37	4 mm. wide 3 mm. deep.			
6-24-37	No ulcer			
6-3-37	5 mm. wide, 4 mm. deep.	9-6-37	Recurrent ulcer with surrounding inflammation.	Slight inflammatory reaction about ulcer.
9-24-37	5 mm. wide, 2 mm. deep.	9-24-37	Ulcer definitely larger.	Improving chronic hypertrophic gastritis.
10-10-37	7 mm. wide, 3 mm. deep.	10-15-37	Ulcer about the same size.	No hypertrophic gastritis; slight superficial gastritis.
		10-27-37	Ulcer unchanged.	Chronic hypertrophic gastritis about ulcer.
11-0-37	5 mm. wide, 4 mm. deep.	11-10-37	Ulcer smaller.	Superficial chronic gastritis of antrum and upper part of stomach.
11-27-37	3 mm. wide, 2 mm. deep.	11-24-37	Healing ulcer.	Slight superficial gastritis of upper part of stomach.
12-7-37	No definite ulcer seen.	12-6-37	Almost-healed ulcer.	Slight superficial gastritis of upper part of stomach.
12-24-37	3 mm. wide, 2 mm. deep.	12-11-37	Very tiny ulcer — 2 mm.	Slight superficial gastritis of upper part of stomach.
1-20-38	No ulcer	1-13-38	Healed ulcer of angle.	Slight superficial gastritis of upper part of stomach.
		2-2-38	No ulcer.	Marked superficial gastritis.
2-11-38	Esophageally, no ulcer seen. Film shows shallow ulcer, 3 mm. wide, 3 mm. deep.			

The roentgenologist (FET) described persistent narrowing of a stomach and pyloric antrum at every examination except the last one when it had apparently disappeared.

Fig. 9 (Case 11). Note the gradual decrease in the size of the ulcer from July, 1934, to its disappearance in December, 1934; the recurrence at the same site in April, 1937; the progressive increase in size to November, 1937, and the subsequent disappearance of the niche.

familiar with the appearance of the lesion, it was shown that most of these lie in the lesser curvature and slightly on the posterior wall. I have done all my own fluoroscopy in my private practice, for a good many years. I have seen about 570 ulcers in our office. In the last eight years we saw 271. During that period of time we have had a little over forty gastric ulcers, so the incidence between gastric and duodenal ulcer was about 12 or 13 to 1.

We have always been impressed by the difference in the behavior of gastric and duodenal ulcer. It seemed to me that gastric ulcer occurred more suddenly, had a more typical history and, furthermore, on fluoroscopic examination was much more prone to change rapidly, so much so today that we insist in gastric ulcer first on complete bed rest; secondly, on a two-week check-up to observe the crater of the ulcer.

It is interesting to note that Dr. Palmer happened to say, regarding the changes in the size of the crater, changes which neither the condition nor the symptoms of the patient might suggest—it is our own experience that in gastric ulcer recurrence is more frequent. They frequently recur in the same site.

I know one woman from Trenton who had a recurrence four different years in succession, each time on the lesser curvature, each time about as big as the thumb. The question is: What to do to prevent the recurrences, and here in the hospital we take the serious cases with large craters and, if they don't quickly respond to ambulatory treatment, we carry on the drip method. I don't believe any of these, after two weeks with drip method would have gotten any larger, and most of them would get smaller, or altogether disappear.

There is another point that we have discussed all afternoon, the question of peptic ulcer. What does it mean? Is it chronic disease or a *maladie constitutionale*? In any case, I feel we can say: These people have to modify their method of living. They are given a mimeographed sheet, and they take five meals a day always, but beginning around the middle of September, and they are told to take ordinary precaution as well as some neutralizing substance and it is interesting to see how they are controlled. It is the method of living that counts most in the control of the lesion.

Once more I want to express my appreciation of this

CASE 8

A. K., Female, Age 63, Unit No. 148736, X-ray No. 47109

The patient gave a history of epigastric distress appearing thirty years before admission, lasting two years, re-appearing seventeen years later, and then persisting intermittently until her admission to the hospital April 1, 1936. She was discharged on management, symptom-free, April 18, 1936. Her adherence to the treatment was only partial and spasmodic. Slight distress recurred from time to time, and promptly disappeared upon the resumption of a more rigid management. Maximum free acidity (histamine) 49. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
4-2-36	Gastric ulcer just below cardia; 5 mm. wide, 4 mm. deep.	4-4-36	Deep penetrating ulcer high on lesser curvature converging folds.	Mucosal hemorrhage, one hemorrhagic erosion.
4-16-36	No crater found.	4-17-36	Ulcer shallow, bleeding.	Small erosion on anterior wall of fornix.
5-27-36	Ulcer in same place, 3 mm. wide, 1 mm. deep.	5-27-36	Ulcer almost healed: star formation of folds.	Slight superficial gastritis above ulcer.
		6-17-36	Ulcer smaller: margins hyperemic; radiating folds.	Slight superficial gastritis above ulcer.
7-17-36	3 mm. wide, depth?	7-17-36	Punched-out, yellow ulcer.	Marked superficial gastritis and antrum.
		8-5-36	Ulcer seen as shallow superficial erosion with five converging folds.	Normal.
10-23-36	10 mm. wide, 10 mm. deep.	10-28-36	Ulcer shallow—about dime size.	Mucosal hemorrhages above ulcer.
12-22-36	3 mm. wide, 3 mm. deep.	12-10-36	Scar or shallow erosion?	Hemorrhages in normal mucosa; slight circumscribed hypertrophic gastritis in fornix.
2-13-37	No ulcer found.			
3-25-37	No ulcer found.	3-17-37	Irregular elliptical small ulcer, radiating folds less marked.	Normal.
		4-14-37	Small erosion at site of former ulcer with marked converging folds.	Normal.
5-15-37	No ulcer—4 mm. niche?	5-12-37	Shallow ulcer about 4 mm. wide.	Mucosal hemorrhage in upper portions.
6-23-37	No ulcer seen.	6-23-37	Crater a little larger.	Chronic hypertrophic gastritis of lesser curvature about the angle.
9-3-37	5 mm. wide, 2 mm. deep.	9-1-37	Crater easily 1 cm. wide	Beginning hour glass.
		12-2-37	Small ulcer, converging folds.	Atrophic gastritis of antrum; beginning hour glass.
1-10-38	No ulcer seen.	1-5-38	Small ulcer.	Slight hypertrophic gastritis in upper part of stomach.
		2-9-38	Healed gastric ulcer scar.	Four mucosal hemorrhages on normal mucosa of lesser curvature.
		2-28-38	Healed ulcer.	Mucosal hemorrhage.
		3-10-38	Normal gastric mucosa.	
3-15-38	No ulcer.	3-29-38	Healed ulcer scar.	No inflammation; hemorrhage of the normal mucosa; first stage of hour glass stomach.

Fig. 10 (R. S., Unit No. 162228, protocol not given): Duodenal Ulcer. Note the definite progressive enlargement of the ulcer from January 28 to July 28 and its subsequent decrease.

Fig. 11 (Case 12). Note the disappearance of the ulcer from December 16, 1936, to April 7, 1937; its reappearance at the same site June 30, 1937, and disappearance by October 7, 1937; and the appearance of a new ulcer below the angulus March 1, 1938, still present April 19. Gastroscopic confirmation is available for all examinations except that of June 30, 1937.

perfectly beautiful paper. I have never seen a better one.

DR. SARA M. JORDAN (Boston, Mass.): I should like to say a few words to congratulate Dr. Palmer, because to me this paper is a real joy. We are able to corroborate so many of the X-ray findings which he has, showing the recurrence of ulcer, particularly the gastric ulcer, in its original site, also the increase in size of gastric ulcers, but we haven't these striking paintings of the gastroscopic findings which I hope Dr. Wilkerson will help us to get from now on.

The increase in size and the recurrence I think are, in our experience, very definite entities. I should like to ask Dr. Palmer if, when recurrence occurs in a lesion on the posterior wall of the stomach, he becomes alarmed about a change from benignity to malignancy. In two of our cases I am very certain a gastric benign lesion was first present. Later, in the same location, after recurrence of the ulcer twice, a malignant lesion occurred. We, therefore, feel worried about those on the posterior wall because it is often so difficult to heal them after they recur or become adherent to the pancreas.

Dr. Palmer showed us pre-pyloric benign lesions. The benignity of any prepyloric lesion has been disputed so often it is a pleasure to see it so well demonstrated here. We have seen many benign lesions where we have had ample proof they had healed and proved their benignity in that way, and Dr. Palmer has shown us today that in his experience also this is true.

Dr. Sidney Portis in a paper given two years ago, showed by autopsy findings that a pre-pyloric scar was very often present where no pre-pyloric lesion was ever

CASE 9

T. K., Male, Age 52, Unit No. 3265, X-ray No. 1562

When seen on November 19, 1935, the patient gave a history of periodic epigastric distress of ten years' duration. He followed his treatment only fairly well, but did not admit distress in 1936 or 1937 except for a slight amount in September of 1936 in spite of the recurrent crater demonstrated roentgenologically in July, 1936, and again in May, 1937. He developed pulmonary tuberculosis in April, 1937, and then, during hospitalization, followed his ulcer program more faithfully. Maximum free acidity (control aspiration) 60. Gastroscoy was not performed, but the roentgenologic findings are tabulated:

X-RAY		GASTROSCOPY	
		Ulcer	Mucosa
5-25-28	Normal stomach and duodenal bulb.	(Gastroscopy not performed).	
11-19-35	Gastric ulcer, prepyloric, lesser curvature, 10 mm. wide, 5 mm. deep.		
12-17-36	Crater, small, 2 mm. wide, 1 mm. deep.		
1-17-36	Crater estimated as about 4 mm. wide.		
3-10-36	No crater found—marked scarring.		
7-7-36	Recurrent ulcer at same site, 6 mm. wide, 5 mm. deep.		
10-22-36	Crater gone.		
4-29-37	Small crater at original site, 3 mm. wide, 3 mm. deep.		
5-14-37	Crater estimated as 4 mm. wide.		
6-7-37	No ulcer.		
3-24-38	No ulcer.		

Fig. 12 (Case 12). Note the disappearance of the ulcer on the angulus and the formation of the new ulcer in the antrum. The chronic hypertrophic gastritis is well shown.

suspected from the history of the patient, and that may be of some help in the diagnosis of the pre-pyloric narrowing which Dr. Palmer mentioned. Possibly a small ulcer with scar may have been present there.

DR. CHESTER M. JONES (Boston, Mass.): I should like to raise a question not entirely germane to the subject. In Dr. Schindler's book on gastroscopy, he makes the statement that it is very uncommon and practically a rarity that a peptic ulcer occurs on top of hypertrophic gastritis. It would seem to me, if I have understood Dr. Palmer correctly, that he has presented at least one case which showed just that; namely, a typical, chronic peptic ulcer, occurring in the case of hypertrophic gastritis. It seems to me that it is quite possible for gastric ulcers occasionally to occur on top of a chronic gastritis of the hypertrophic type.

DR. WILLIAM A. SWALM (Philadelphia, Pa.): On the importance of correlating the gastroscopic, the roentgenologic, and clinical diagnoses, we had one difficult case in which there was a gastric ulcer and we saw this gastric ulcer heal up on repeated observations gastroscopically. Subsequently the patient developed a duodenal ulcer, and we were not sure whether the gastric ulcer remained cured. On gastroscopy we found the gastric ulcer had remained healed, and on subsequent observations it has remained healed, and the duodenal ulcer symptoms have been also cleared for the past six months; therefore, I just want to go on record to mention the importance of gastroscopically examining some of these cases.

May I ask one other question? I should like to ask how he feels about the craters of these ulcers, roentgenologically, and anatomically. Are they the same size, and why are they not?

Dr. Ryle of Guy's Hospital in London, showed us a case in which at autopsy the size of the ulcer did not correspond with that seen roentgenologically. I wonder if the essayists can explain this discrepancy.

DR. RUDOLF SCHINDLER (Chicago, Ill.): May I answer the question of Dr. Jones. I still do believe that the small ulcerations of chronic hypertrophic gastritis do not change to true gastric ulcers. I never have observed that, at least, but, on the other hand, in chronic gastritis, the ulcer sites may be surrounded by chronic gastritis, hypertrophic or superficial and even at times atrophic

changes may be seen in the upper portions of the stomach. The question is whether this gastritis is primary and the ulcer is secondary. I believe that the ulcer is primary.

DR. B. B. VINCENT LYON (Philadelphia, Pa.): Entirely from the clinical point of view I should like to ask Dr. Palmer in exhibiting these regressions and exacerbations, enlargements and diminutions, and healing of ulcer in the clinical sense, were these patients treated in what Dr. Palmer would consider an adequate medical sense? If they did this despite adequate medical treatment, then I believe it opens up a new point of view in regard to all of our present ulcer management.

DR. WALTER L. PALMER (Chicago, Ill., closing the discussion): The discussants have been very kind and I wish to thank them, particularly Dr. Jordan and Dr. Rehfuess.

With regard to the question raised by Dr. Jordan, of malignant degeneration of ulcers on the posterior wall, we are very much worried about the possibility that all of these lesions may be malignant until we have had an opportunity to prove them otherwise. I should like to discuss the relationship between gastric ulcer and gastric carcinoma, but there is scarcely time for that this afternoon. Specifically, we have had one case considered to be benign in which death occurred subsequently from gastric carcinoma. For reasons which I cannot give in detail now, the pathologists think that the ulcer was benign and that the carcinoma may have arisen independent of the ulcer. I asked Dr. Wells, specifically, "Do you think in this case there is any reason to believe that the carcinoma arose in the ulcer?" He said he had no way of telling.

The ulcer was an old, penetrating one and the patient died of carcinoma of the type that invades the entire wall and the entire stomach. It seems impossible to decide in this case whether the carcinoma arose in the ulcer or elsewhere in the stomach.

Dr. Schindler has spoken on the question, raised by Dr. Jones, of the relationship between hypertrophic gastritis and ulcer, and I shall not add to that.

With regard to Dr. Swalm's question as to the correlation between the size of the crater as seen roentgenologically and that found anatomically, I had the privilege of discussing this subject with Prof. Hans Heinrich Berg when he was in this country attending the Radiological Congress, and I think it is fair to say he feels there is a definite and exact correspondence if one takes the ulcer immediately after resection and freezes it to prevent the disappearance of edema. When an ulcer is removed at the operating table and fixed a few hours later in the usual fashion, the edema and inflammatory swelling rapidly decrease, and hence the size and depth of the crater in the anatomical specimen appear to differ from the dimensions of the roentgenologic niche more than they actually do.

With regard to Dr. Lyon's question as to whether or not these patients were under adequate treatment, I don't know. I know they were often under what I should consider to be inadequate treatment. The problem, to my mind, is, What is adequate treatment? Usually there was not much difficulty in getting the crater to decrease in size when the patients were in the hospital under controlled conditions. In several of the cases in which the ulcer decreased in size, it did so when the patients came

CASE 10

J. B., Male, Age 65, Unit No. 116703, X-ray No. 36488

The patient gave a story of epigastric distress of six months' duration only. He entered the hospital for treatment November 14, 1934, and was discharged symptom-free December 12, 1934. He has followed a "modified Sippy" program and has not had a definite recurrence of symptoms in spite of the reappearance of the crater in February, 1935, and again in December, 1935. Maximum free acidity (Ewald) 70. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
11-19-34	Gastric ulcer 2 cm. proximal to pylorus, 13 mm. wide, 6 mm. deep.	11-21-34	No ulcer seen (pylorus and prepyloric portion of lesser curvature not seen).	Normal.
11-23-34	10 mm. wide, 7 mm. deep.	12-14-34	Benign ulcer, anterior wall near angulus.	One small mucosal hemorrhage; no inflammation.
12-7-34	8 mm. wide, 2 mm. deep.	12-27-34	Depth of ulcer diminished.	Hypertrophic gastritis about ulcer.
12-31-34	No ulcer found.	1-18-35	Ulcer shallower, irregular.	No inflammation about ulcer; slight superficial gastritis of upper parts of lesser curvature.
2-16-35	Ulcer in same place. 2 mm. wide, 6 mm. deep.	3-16-35	No ulcer seen. Pylorus and part of lesser curvature of antrum seen.	Mucosal hemorrhages.
6-29-35	No ulcer found.			
12-14-35	Ulcer at original site. 10 mm. wide, 5 mm. deep.			
2-5-36	Ulcer much smaller. 3 mm. wide, 1 mm. deep.			
4-4-36	No ulcer found.			
10-24-36	No ulcer found.			
2-19-38	No ulcers; good film identical with that of 10-24-36.			

CASE 11

W. R., Male, Age 53, Unit No. 105146, X-ray No. 33471

The patient entered the hospital May 30, 1934, because of hematemesis and melena. Epigastric pain had been present at intervals for many years. In spite of the recurrent ulcer found in a routine examination in April, 1937, symptoms did not appear until November, 1937, when the lesion increased rapidly in size. Complete healing apparently occurred in February, 1938. Deep radiation therapy was administered for ten days in daily doses of approximately 300 r (measured in air) alternately through anterior and posterior portals directed at the upper two-thirds of the stomach, the total dosage being 2953 r, the last treatment being given November 2, 1937. Maximum free acidity (histamine) 94. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
7-9-34	Gastric ulcer, lesser curvature, 33 mm. wide, 17 mm. deep.			
8-1-34	20 mm. wide, 9 mm. deep.			
8-21-34	19 mm. wide, 7 mm. deep.	8-21-34	Ulcer, lesser curvature, above angulus with one converging fold.	Slight hypertrophic gastritis above ulcer; one pigment spot, posterior wall.
10-12-34	9 mm. wide, 4 mm. deep.	10-10-34	Ulcer not seen; gray atrophic area thought to be ulcer scar.	Many erosions, lesser curvature, with one flat erosion.
		10-19-34	Small ulcer crater.	Superficial gastritis of whole stomach.
		11-7-34	Ulcer not found.	Gastritis much improved; swollen folds only on lesser curvature.
11-23-34	9 mm. wide, 3 mm. deep.	11-21-34	Ulcer not found.	Gastritis of upper parts of lesser curvature only.
12-19-34	No ulcer.	12-17-34	Ulcer not found.	One small gastritic nodule in anterior wall.
		1-31-35	Ulcer not seen.	Multiple hemorrhages in normal mucosa of lesser curvature and anterior wall.
		7-8-35	Ulcer not seen.	One mucosal hemorrhage, anterior wall.
9-27-35	Radiating folds; scar.	10-30-35	Ulcer not seen.	Normal stomach.
		4-13-35	No ulcer.	Normal.
4-13-37	3 mm. wide, 4 mm. deep.	4-28-37	Two small ulcers at angulus.	No gastritis.
4-23-37	4 mm. wide, 3 mm. deep.	5-12-37	No ulcer seen.	
5-25-37	2 (or 3?) small ulcers, 3 mm. wide, 2 mm. deep.	6-2-37	No ulcer seen.	Extensive hypertrophic gastritis of lesser curvature.
6-23-37	5 mm. wide, 4 mm. deep.	6-23-37	No ulcer seen.	Normal mucosa.
		7-21-37	No ulcer seen.	Normal mucosa.
		9-1-37	No ulcer seen.	Lower third not seen — mucosa normal.
9-22-37	4 mm. wide, 3 mm. deep.	9-29-37	No ulcer seen.	Normal mucosa.
10-21-37	7 mm. wide, 5 mm. deep.	10-27-37	No ulcer seen.	Normal mucosa.
11-23-37	80 mm. wide, 15 mm. deep.	11-22-37	Giant ulcer; diameter estimated at 3.5 cm.	No inflammation; mucosal hemorrhage in normal mucosa.
11-30-37	30 mm. wide, 17 mm. deep.	12-2-37	Gigantic ulcer.	No inflammation.
		12-11-37	Benign healing ulcer with reddened halo, decreasing in size.	
12-21-37	20 mm. wide, 10 mm. deep.	12-20-37	Ulcer decreasing in size.	Slight inflammation about ulcer.
		12-29-37	Ulcer definitely smaller and shallower.	Mucosa normal.
1-5-38	12 mm. wide, 7 mm. deep.	1-10-38	Ulcer definitely smaller and shallower.	Mucosa normal.
1-20-38	8 mm. wide, 5 mm. deep.	1-21-38	Ulcer diameter estimated at 1 cm.	Mucosa normal.
2-3-38	5 mm. wide, 3 mm. deep.	2-11-38	Ulcer very shallow.	Mucosa normal.
2-24-38	2 mm. wide, 2 mm. deep.	2-25-38	Ulcer not seen.	Slight superficial gastritis.
3-3-38	No ulcer.			
4-7-38	No ulcer.	4-5-38	No ulcer seen.	

CASE 12

J. C., Male, Age 31, Unit No. 164495, X-ray No. 53042

The patient gave a history of periodic epigastric pain of eight years' duration with at least two massive hemorrhages. He entered the hospital December 15, 1936, and was discharged January 2, 1937. In spite of "modified Sippy" management, slight distress recurred in March and April, 1937, but was controlled by temporarily returning to the more strict program. In June, 1937, the pain again recurred, but disappeared upon resuming management and has not recurred to date (April 23, 1938) even though the ulcer apparently is not yet completely healed. Deep radiation therapy was administered for ten days in daily doses of approximately 300 r (measured in air), alternately through anterior and posterior portals directed at the upper two-thirds of the stomach, the total dosage being 2951 r, the last treatment being given July 19, 1937. Maximum free acidity (histamine) 75. The roentgenologic and gastroscopic findings were as follows:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
12-16-36	Gastric ulcer just above the angulus, 10 mm. wide, 8 mm. deep.	12-19-36	Small ulcer, angulus; perhaps a second ulcer higher on lesser curvature.	Hypertrophic gastritis, posterior wall.
12-31-36	No ulcer.	1-20-37	Healing ulcer.	Marked pallor of mucosa and patchy hypertrophic gastritis.
2-2-37	No ulcer.	2-3-37	Unusual scarring with radiating folds.	Hypertrophic gastritis, lesser curvature about the scar.
4-7-37	No ulcer.	4-7-37	No ulcer.	Marked chronic hypertrophic gastritis, lower third of body, with swollen folds, crevices, and mottling.
6-30-37	Gastric ulcer just above the angulus, 7 mm. wide, 4 mm. deep.	7-14-37	No ulcer.	Hypertrophic gastritis.
10-7-37	No ulcer.	9-20-37	No ulcer.	Mucosal hemorrhages and pigment spots; superficial gastritis after X-ray; minimal atrophic gastritis.
		10-15-37	No ulcer.	
		2-23-38	Ulcer, lesser curvature of antrum beyond angulus.	Severe hypertrophic gastritis about ulcer.
3-1-38	Very small ulcer, about 3 mm. wide, just below the angulus.	3-31-38	Small erosion in place of former ulcer; beginning scarring.	Remnants of gastritis.
4-19-38	Fluoroscopy, no ulcer; film suggests shallow ulcer, 2 mm. wide at angulus.			

Persistent narrowing of the antrum was described in each and every roentgenologic examination.

CASE 13

S. F., Male, Age 47, Unit No. 134295, X-ray No. 42233

The patient, in very broken English, gave an indefinite story of epigastric distress of two years' duration. Roentgenologic examinations were negative in August and October, 1935. Following the roentgenologic and gastroscopic demonstration of a gastric ulcer in March, 1936, ulcer therapy was instituted and complete symptomatic relief obtained, followed by the disappearance of the crater. In December, following a cold, the distress and the crater recurred, but soon disappeared upon the resumption of treatment. The patient then continued a "modified Sippy" program without recurrence of the distress or of the ulcer to date (April 23, 1938). Maximum free acidity (Ewald) 29. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
8-13-35	No ulcer; thickened, stiffened rugae suggested gastritis.			
10-28-35	No ulcer.			
3-20-36	Gastric ulcer 3 cm. above angle, 18 mm. wide, 7 mm. deep.	3-20-36	Deep crater-like ulcer above angulus, lesser curvature.	No inflammation around ulcer; slight superficial gastritis around upper part of lesser curvature.
		4-3-36	Ulcer shallower.	One mucosal hemorrhage; superficial gastritis only of upper parts of body.
		4-13-36	Ulcer very shallow; about $\frac{2}{3}$ size of last examination.	Extensive mucosal hemorrhages of anterior and posterior walls of body; no definite gastritis except questionable area around ulcer.
		4-27-36	Ulcer linear, about $\frac{1}{2}$ the size of the first examination.	Two hemorrhagic spots, normal mucous membrane.
		5-18-36	No ulcer; no scar seen.	Four mucosal hemorrhages, lesser curvature.
		6-1-36	Shallow ulcer.	Mucosal hemorrhages.
		7-22-36	No ulcer seen.	Mucosal hemorrhages turning into pigmentation; no inflammation.
		9-9-36	No ulcer or scar seen.	One hemorrhage, middle part of lesser curvature.
11-28-36	No ulcer.			
1-5-37	No ulcer.	1-6-37	Small gastric ulcer 2 cm. above angulus.	Slight gastritis about the ulcer.
1-9-37	Small ulcer, same place, 4 mm. wide, 3 mm. deep.	1-20-37	Very small ulcer, barely visible.	Marked inflammation about the ulcer; hemorrhagic spots along the posterior wall.
2-15-37	Very small depression, 2 mm. wide, 1 mm. deep.	2-17-37	Ulcer not seen.	Mucosal hemorrhages; no inflammation.
2-25-37	No ulcer.			
5-22-37	No ulcer.			
6-23-37	No ulcer.	6-23-37	No ulcer.	Mucosal hemorrhages.
9-3-37	No ulcer.	9-8-37	No ulcer.	Mucosal hemorrhages.
		11-12-37	No ulcer.	Slight hypertrophic gastritis.
3-8-38	No ulcer.	3-2-38	No ulcer.	Normal mucosa.

The ulcer was always seen at the same point—a spot easily seen with the gastroscope. The possibility that it was overlooked or hidden from view, when not seen, seems very remote.

CASE 14

S. B., Male, Age 54, Unit No. 156058, X-ray No. 49673

The patient had an attack of epigastric pain in 1928 and an ulcer of the stomach is said to have been found at X-ray at that time. The pain apparently disappeared on treatment and did not recur until about July 1, 1936. The patient was admitted to the hospital for treatment August 6, 1936, and discharged symptom-free August 18, 1936. He followed treatment for a few months only. Slight distress, recurring in February, 1937, was relieved upon the resumption of therapy for a few months. In November the distress recurred and the patient was hospitalized from December 31, 1936, to January 22, 1938. Deep radiation therapy was administered for ten days in daily doses of approximately 300 r (measured in air), alternately through anterior and posterior portals directed at the upper two-thirds of the stomach, the total dosage being 3066 r, the last treatment being given January 22, 1938. At present (April 23, 1938) the patient is continuing treatment, has no pain, but the ulcer has not yet healed completely. Maximum free acidity (histamine) 102. The roentgenologic and gastroscopic data follow:

X-RAY		GASTROSCOPY		
			Ulcer	Mucosa
7-23-36	Gastric ulcer just above the angle, 11 mm. wide, 5 mm. deep; duodenal deformity, no crater.			
8-7-36	5 mm. wide, 5 mm. deep.	8-12-36	Deep ulcer crater above angulus.	Hypertrophic gastritis about ulcer; hypertrophic node in m. sphincter antri.; patch of atrophic gastritis in upper parts of anterior wall.
9-1-36	Ulcer not found.	10-14-36	No ulcer seen.	Hypertrophic gastritis of almost whole stomach.
12-22-36	No ulcer; duodenal deformity unchanged.	12-23-36	No ulcer seen.	Unusual combination of hypertrophic gastritis with a patch of atrophic gastritis high on the anterior wall.
5-12-37	No ulcer.	5-5-37	No ulcer.	Two erosions; chronic erosive gastritis, lower part near angle on lesser curvature.
9-23-37	No ulcer.	10-6-37	Shallow ulcer, angulus — shallower and smaller than last year.	Chronic hypertrophic gastritis about ulcer.
1-4-38	5 mm. crater.			
1-5-38	No ulcer.			
1-7-38	No ulcer.	1-10-38	No ulcer.	Severe hypertrophic, hemorrhagic, ulcerative gastritis.
1-21-38	No ulcer seen.			
2-12-38	Ulcer 6 mm. wide.	2-11-38	Ulcer at angulus.	Slight superficial gastritis at fornix.
		2-25-38	Ulcer almost healed — very shallow.	Superficial gastritis about ulcer.
3-17-38	Ulcer 6 mm. wide, 2 mm. deep.	3-11-38	No ulcer.	Superficial and hypertrophic gastritis.
		4-1-38	Gastric ulcer of the angulus.	Slight inflammation around the ulcer.

into the hospital and increased when they went home. I became quite annoyed with one lady after that had happened two or three times and gave her a good scolding with instructions to stay strictly on her management with no more running around to bridge parties. The ulcer then healed and has remained healed to date. Whether this was merely coincidence or the result of scolding, I don't know.

In some of the cases in which there were recurrences, the patients seemed to be following treatment as well as they could. We still use the old Sippy program and the patients assured me that although they were going about their work, they were eating a rather soft diet and were taking milk and cream and powders regularly. In one case, while the patient was in the hospital, the ulcer healed very slowly in spite of this regimen. This was one of the cases I showed with marked antral narrowing and gastric

retention. The retention apparently played a very important role in the delayed healing.

I am sorry that I do not have time to discuss the acid factor in the pathogenesis of ulcer and in the mechanism of pain. It came up for discussion earlier this afternoon. I think you have had enough of it; but with regard to pain, one word, if I may. If anyone studying the subject of ulcer pain will carefully take a patient in pain, empty the stomach, wait for the pain to disappear, then inject 200 cc. of 0.5 per cent hydrochloric acid, wait for pain to develop, take the acid out again, wait for the pain to disappear, then put in an alkali, observe that no pain develops, then take it out and put the acid in once more and produce pain again, he can in a few short demonstrations convince himself that acid does have something to do with the production of pain.

Editorials

THE REGULATION OF GASTRIC EMPTYING

WITHIN the past several years great advances have been made in our knowledge of the mechanisms that regulate gastric motor activity. In contrast with an earlier view that gastric peristaltic waves continue uninterrupted throughout the period of digestion and are not subject to regulatory influences we know now that the gastric tone and the force of gastric peristalsis may be changed by many different stimuli when they are applied in adequate strength to the small or large intestine. Among the conditions within the intestine that affect gastric motor activity are mechanical distention, chemical irritation, the action of hypertonic or hypotonic solutions, and the presence in the intestinal lumen of HCl, fat and the products of protein and of starch digestion.

Since the food substances and the products of their digestion, as well as HCl, are present in the normal gastrointestinal contents, any effect that they may have on gastric motility is likely to be physiologically important. The experimental evidence indicates that such is the case. It has been found that the upper intestine manifests a degree of selective irritability toward these particular substances which enables them to exert their specific influence when present in only moderate concentrations.

Hydrochloric acid and some of the products of protein digestion (1) when present in the small intestine act reflexly, through the vagus innervation, to cause inhibition of gastric tone and peristalsis. The response is known as the enterogastric reflex (2). Contrary to current theory, HCl has, apparently, less to do with the regulation of emptying than have the other substances mentioned (1, 3, 4). Quantitative studies (4) have shown that although HCl is an efficient stimulus for the enterogastric reflex (and for temporary reflex closure of the pylorus), it is generally so diluted or neutralized on passing the pylorus that it seldom reaches an effective concentration in the intestine.

Fat in the intestine also causes inhibition of gastric tone and peristalsis. This is an old observation and the slow emptying of fatty meals is well known. More recently Quigley and Phelps (6) have observed a similar effect due to carbohydrate (sugars) in the intestine. The sugars cause marked gastric inhibition only when present in fairly high concentrations and some observers have questioned whether the gastric inhibition is the result of a specific carbohydrate action or of the hypertonicity of the solutions. We have some data (unpublished) which support Quigley's conclusions and we are convinced that certain carbohydrates, at least, have a specific inhibitory effect on gastric peristalsis when they are present in the upper small intestine.

It is possible that fat and carbohydrate stimulate the enterogastric reflex mechanism but the tendency at present is to attribute their action to an inhibitory substance (enterogastrone) (5) which they liberate from the intestinal mucosa. This substance is carried to the stomach by the blood and inhibits gastric tone and peristalsis as well as gastric secretion. It has

been definitely proved (6,7) that fat and carbohydrate may, under certain conditions, exert their specific inhibitory influence through a humoral mechanism.

With these facts in mind we may describe the regulation of gastric emptying somewhat as follows. Some time after food is taken the stomach begins to pour into the duodenum a complex mixture usually containing, among other things, HCl, proteoses and peptones, products of starch digestion and fat. Presently one or more of these substances accumulates in the intestine in sufficient concentration to excite the enterogastric reflex or to start the liberation of enterogastrone. As a consequence, the tone of the gastric muscle diminishes, the intragastric pressure decreases and peristalsis grows weaker; the emptying will proceed at a slower rate. Thereafter the gastric motor activity may be expected to increase if the emptying fails at any time to keep pace with intestinal digestion and absorption, or to decrease if the reverse occurs.

The fact that competent observers have failed to see such fluctuations in gastric activity, and have indeed remarked on their absence, indicates merely that the regulatory mechanism, like other similar devices in the body, accomplishes its function smoothly and efficiently. Probably, once the rate of emptying is adjusted so as to maintain the concentration of gastro-inhibitory substances in the intestine at or slightly above their threshold concentrations, little further change in the degree of gastric activity is required.

Other factors are, of course, involved in the control of gastric emptying. The initial emptying, for example, is probably determined by conditions quite different from those under discussion here. The conditions responsible for the initiation and augmentation of gastric motor activity have not been mentioned although they are obviously essential in the emptying process. However, taking the initial emptying for granted and assuming the constant presence, during digestion, of a gastric "motor drive" we think that the factors which serve to regulate the activity so as to prevent overloading the intestine are comprised chiefly within the gastro-inhibitory reflex and humoral influences resulting from the presence within the intestine of the food materials and the products of their digestion.

THE FORMATION OF HYDROCHLORIC ACID IN THE STOMACH

ONE of the most remarkable chains of chemical reactions in the body is that which results in the formation of the hydrochloric acid of the gastric juice. On one side of the secreting cells is blood with a pH around 7.2, and on the other side is hydrochloric acid

with a pH around 1.5. This means that during the quick passage of material through a tiny gland the hydrogen-ions are concentrated some 700,000 times. Gastro-enterologists would like to learn something of the mechanism which produces this remarkable transformation, if only because if the chemistry of the process were known, they might see where a monkey wrench would conveniently be thrown into the machinery, and then they might have a good cure for ulcer.

Under the microscope it can be seen that, in the large parietal cells, gastric secretion forms in little canaliculi which run through the cytoplasm. At first glance it would seem to be an easy thing to find out with the help of vital stains, reagents, and indicators where the acid is formed and how the precursors of the acid are brought into the secreting cell, but, actually, the difficulties encountered have been so great and the findings so puzzling and so contrary to expectation that knowledge in regard to the phenomenon is still somewhat fragmentary. Much of the early literature will be found summarized in the articles by Collip (1920) and Dawson and Ivy (1926). Unfortunately, some of the early work was not satisfactory, partly because too much time was allowed to elapse between the death of the animal and the staining of the tissue, and partly because the indicators and reagents used were not entirely satisfactory. Some of the indicators probably did not diffuse well into the cells, or they diffused so slowly that, as they entered, other substances had time to diffuse out. Furthermore, some of the indicators and reagents used were injurious to the tissues being studied.

Theoretically the blood must bring to one side of the secreting cell chlorides which are to be split, with extrusion of the base back into the blood and of the chloride ion into the lumen of the gland. Somewhere along the way this chloride must combine with hydrogen. Actually it has been shown by several observers that the blood leaving the stomach is slightly more alkaline than that going to the stomach, and it contains slightly less chloride.

One would expect, on staining the tissues with a suitable reagent, to show large amounts of chlorides entering, filling, or leaving the gastric cells, but actually, the efforts to do this have so far been disappointing. In a recent paper Gersh (1938) described what appears to be the best work done so far on the problem. He studied bits of tissue removed quickly from the stomach of dogs and frozen in liquid nitrogen so as to put a stop instantly to all chemical processes. He found, as López-Suárez (1912) and Lison (1936) had done years ago, that in the resting glands of a fasting animal there is little sign of chlorides in the cytoplasm of any of the five types of cell. Traces could be identified only in the granules of the zymogenic or "chief" cells. Chloride was present in the lumen of the gland along the free border of the cells, and it was present in considerable amounts in the foveola or mouth of the gland and on the surface epithelium. It was evenly distributed through the connective tissue spaces of the lamina propria mucosae and the tela submucosa. Strangely, the distribution of the chloride in the actively secreting mucous membrane did not differ essentially from that in the resting tissue. The only difference was that the amounts were greater.

One possible explanation for these curious and puzzling observations is that the chloride ions are so

closely bound to some protein that they do not combine with the reagent. It is possible also that this hypothetical protein chloride is extruded from the cell as rapidly as it is formed. Curiously, there is no more chloride in the parietal cell than in the supposedly non-acid-forming cells, and as Gerch said, his experiments offer no support to the view that the acid is formed exclusively in the parietal cell.

Collip (1920) concluded from his studies that chloride ions are not taken up by the parietal cells until these cells go into action. He noticed that the interstitial tissue of the mucosa is rich in chlorides and other salts, and he thought that the parietal cells probably drew upon this reservoir. Collip concluded that the cytoplasm of the parietal cells is acid at certain stages of activity, but this he thought was due to the presence of sodium acid phosphate. He was inclined to agree with Maly's theory of the production of hydrochloric acid from sodium chloride and acid sodium phosphate. He doubted if any hydrochloric acid was formed in the parietal cells themselves, but thought it was formed in the canaliculi. In this view he agreed with FitzGerald.

According to Harvey and Bensley (1912-13), who also used a histologic technic, the fluid in the canaliculi of the parietal cells was alkaline, and an acid reaction was found only on the surface of the stomach. They suggested that the parietal cells probably secrete a chloride of some organic base which, on reaching the mouth of the gland, yields free hydrochloric acid.

Dawson and Ivy showed that gastric cells cut off from the circulation change so rapidly in their reactions to indicators that much of the work of the older investigators cannot be trusted. To avoid such postmortem changes Dawson and Ivy injected dye into the living animal and then cut out for immediate examination small sections from the exposed gastric mucosa of a Pavlov pouch. They found that the parietal cells are those most intimately concerned with the elimination of certain dyes from the gastric wall. Unfortunately, a comparison of the chemical structure of the dyes excreted with that of the dyes not excreted did not throw any light on the nature of the chemical processes within the cells. No chemical properties appear to distinguish the one group of dyes from the other. There was no storing of the dyes in the granules of the cells; they apparently were extruded as fast as they entered.

Dawson and Ivy concluded from their studies that both the cytoplasm and the canaliculi of active parietal cells had a pH somewhere between 3 and 6.8. They suggested that there might be a partial dissociation of the hydrogen and chloride atoms from their precursors in the cell and a complete dissociation in the canaliculi or at the surface film separating the cytoplasm from the lumen of the canaliculus. Their evidence suggested that the secretion, as it comes from the parietal cells, must be concentrated in the lumen of the gland perhaps by the absorption of water.

Much against this idea of concentration is the observation by Stöhr (1882), Zimmermann (1925), Harvey and Bensley, and Hoerr and Bensley, to the effect that the secretion as it forms in the canaliculi is viscid and jelly-like. It is coagulable with heat and alcohol, and it stains faintly with Millon's reagent, indicating the presence of tyrosine. As it passes down the lumen of the glands this gummy substance can be seen sometimes to break up into little cylinders or

BOOK REVIEWS

droplets, which eventually are dissolved perhaps by secretions from some of the other cells in the glands. The impression left is that the acid is secreted in the form of a protein hydrochloride which, on being hydrolyzed, yields up the acid.

Recently Bensley, Gersh, and Hoerr decided that a good way in which to get rid of postmortem changes in the cells would be to freeze the tissues instantly in pentane at a temperature of -131°C . or in isopentane at -195°C . Using this technic on material obtained from recently-fed rabbits injected with neutral red, Hoerr and Bensley found the canaliculi of the parietal cells stained a bright yellow, which indicated an alkaline reaction. The cytoplasm was pale yellow, and the contents of the lumen of a gland in its depths was an intense orange-red; from the neck of the gland on out the secretion was crimson, or highly acid.

Because of the possibility that the indicators used do not diffuse satisfactorily into the tissue, the most convincing evidence as to the reaction of the cytoplasm of the parietal cells is that obtained by Chambers when, in 1915, he injected neutral red into these cells with the help of a micropipet. When a very minute drop of dye was injected, it diffused throughout the cell without attacking the nucleus. Soon it faded out of the protoplasm, and orange-yellow or alkaline vacuoles appeared under the edges of the cell. These vacuoles fused to form canaliculi. Within the lumen of the gastric gland there appeared first an orange color which shaded farther along into the red. When the dye was injected directly into the lumen of the gland near the parietal cells, the canaliculi sometimes took on an orange-yellow hue. Farther out in the lumen of the gland the color was a neutral red. These results convinced Chambers that the secretion of the parietal cell is neutral if not actually alkaline. This conclusion is similar to that of Hoerr and Bensley, and French (1918).

Another way of estimating the acid-base balance in the gastric mucosa would be to determine the carbon dioxide equilibrium of the tissue. On doing this Irving and Wilson (1932) found the tension in the resting mucosa to be about 60 mm., and the CO_2 content about 32.0 volumes per cent, which suggests a pH of about 7.0. In an active mucosa the pH may have been slightly

on the acid side. Interestingly, the pH of the acid-forming mucosa in the fundus appeared to be the same as that of the nonacid-forming pyloric mucosa.

The conclusion from all this is that chloride ions accumulate to some extent in the tissues about the gastric cells. They go through these cells so rapidly that no accumulation takes place during the process of secretion. The parietal cells secrete a gummy substance which is probably a protein hydrochloride, and as this goes through the lumen of the gland, it is broken down with the formation of hydrochloric acid. During the process of secretion the cytoplasm of the parietal cell remains practically neutral.

Book Reviews

Post-Operative Radiologic Exploration of the Main Biliary Duets (L'exploration radiologique post-opera-toire de la voie biliaire principale). By B. Desplas, P. Moulouguet and P. Malgras. A book of 120 pages with 40 illustrations. Masson & Company, Paris, 1938.

THE X-ray examination of the biliary tract following operation on the gall bladder has been unknown prior to 1922. In recent years, angiocholecystography has appeared very rich in possibilities to surgeons who have experimented with it. Palpation and catheterization of the bile ducts during operation represent much less accurate procedures due to anatomical complexity of the region and to various dangers of introducing a sound, blindly.

In a concise and lucid book, the authors describe their technique of angiocholecystography, the normal

radiological aspects of the biliary tract and their different pathological expressions.

Primarily they discuss the choice of the radio-opaque liquid. After criticism of the different opacifying substances such as bismuth, barium, sodium bromide, thorium, lipiodol, abrodyl, etc. . . preference is given to tenebryl (di-iodo-methane-sulfonate of sodium) used in venous pyelography. Tenebryl avoids inconveniences such as a too high viscosity and opacity met with in the other proposed media.

Instrumentation consists only in a 20 cc. syringe with a display of tips easily connected with the draining tube. The examination should take place between the fourth and tenth day after cholecystotomy. The patient should be kept fasting from the previous evening.

Radiographs should be taken with films over and under the patient, in the supine posture, with the radiation beam centered where the sound penetrates the abdominal wall.

Ten to twenty cubic centimeters of opaque liquid are sufficient in most cases. A skiagram of the region, previous to injection, is recommended in order to reveal a stone eventually overlooked or any other foreign body likely to mislead interpretation.

Immediately after injection, the first film is taken. Then, the catheter is closed with an hemostatic forceps and after a few minutes interval, a second picture is taken, shortly followed by a third film.

Thus, information is obtained on the patency of the bile ducts and on the permanency of really pathological aspects. Cholecystotomy avails best results with cholangiography; but, choledochotomy with the use of a T catheter may also insure good pictures provided certain care is taken.

A thorough knowledge of the normal aspects of the biliary tree is necessary before interpreting the pathological pictures. This requires a rather long training because normal bile ducts are variable.

The injection under the fluoroscope permits an evaluation of the function of the fistulised gall bladder while films bring out accurate anatomical data.

Immediate and remote incidents and accidents of cholangiography present little severity. They are limited to pain during the injection when too high a pressure is used, malaise with nausea, vomiting, subicterus and fever, when a strict fasting has not been observed. Iodism with lipoidal, tenebryl and similar products are not to be feared.

Retention of the substance in the bile ducts is a rare and inconsequential event. The method meets with no other contra-indication except jaundice due to hepatitis.

Following a description of the main and secondary bile ducts, pathological descriptions are exposed with complete details.

Reading and rereading such a book brings out the marvelous possibilities of cholangiography and makes one realize that the pathology of the bile tract is not so simple as usually considered and that everything is not done after the gall bladder has been removed or opened.

With the aid of cholangiography, unrecognized calculi may be detected; patients suffering with severe angiocholitis will be operated on again; residual distention of the main ducts or its stenosis due to coexisting pancreatitis may be discovered; in chronic jaundice by retention without obstruction, the bile tract may be explored so that one can differentiate cases where hepatitis is the only cause from those where choledochitis coexists.

External compression of the terminal choledochus by a cyst or a swelling of the pancreas may be identified; certain biliary or pancreatic cancers, in their

early stages, may be evidenced; finally, in biliary fistulas, the nature and site of the obstacle may be determined while being ignored during operation.

The book contains about forty very good radiograms all clearly explained by annexed drawings.

Albert Jutras, Montreal, Canada.

Introduction a la Chirurgie Digestive. By E. E. Lauwers. Preface—Prof. P. Duval. 220 pages. Masson & Cie, Paris, 1938.

NOWHERE as in this special field shall "functional repair, and not simple anatomical reconstruction, determine the outcome of a surgical intervention of the gastro-intestinal tract."

There is much to be said for this work, which should appeal to the qualified surgeon and those on the threshold of a surgical career in gastro-enterology. The importance of a thorough and extensive knowledge of basic physiological principles which go to build a sound foundation for this "special type" of surgery is stressed throughout the volume, which may be considered more as an essay on function than as a complete study of surgery of the gastro-intestinal tract. Without being too didactic, it has steered a middle course and has unfolded the numerous biological problems instead of describing intricate and non-interesting operative procedures.

This work should prove of material value to the student as well as the experienced surgeon in indicating the numerous pitfalls and problems that this new field presents. The author has proven himself an excellent teacher with a profound knowledge of general surgery and surgical principles, based on the new conception of "physiological versus anatomic surgery."

The author speaks enthusiastically of results obtained by fundusectomy in gastric ulcer and has not been highly elated by results obtained by more radical surgery. Gastro-enterostomy, to most surgeons, seems to be the operation of choice. We do not subscribe entirely to this opinion. A most interesting chapter on cancer of the large bowel includes a discussion of colectomy in one stage, and the better results achieved by Rankin's procedure as compared to the Mikulicz method in dealing with cancer of the transverse or pelvic colon.

Short topics on laboratory tests and explorations of the gastro-intestinal tract, precancerous state, tuberculosis of the intestine, chronic appendicitis, diverticulitis, fistulae of the intestinal tract, and pruritis ani complete the first part of the work.

The second part is given to a short survey of the functional tests for and surgery of the liver and biliary tract, icterus and its classification, and surgery of the pancreas and spleen.

Antonio Cantero, Montreal, Canada.

Abstracts

AMERICAN PUBLIC HEALTH ASSOCIATION

The scientific program of the 67th Annual Meeting of the American Public Health Association in Kansas City, Mo., October 25-28, which will engage the attention of more than 3500 of the nation's health authorities, indicates how closely the organization's Program Committee has been following national trends in public health progress.

There is considerable emphasis on the five major diseases which are being attacked throughout the land with government funds. The grave problem of maternal and infant mortality receives its share of attention. A special session is devoted to a discussion of "Public Health Aspects of Medical Care" which it is expected will be one of the most significant of the entire conference, with exponents of the National Health Program, spokesmen for organized medicine and representatives of the newly-recognized medical consumers, the public, on the platform.

The recruiting and training of public health personnel for the specialized tasks the expansion of health services are creating and for which trained workers are seriously lacking is a major note in the varied program. The health department as a business organization is a new concept which will be treated by the special session method. Administrative procedures, accounting measures, including cost-accounting, will be considered. Many health departments are now on a parity with million-dollar enterprises and special techniques and formulae for the conduct of the big business of public health are definitely needed.

More than 400 papers and reports will be presented and discussed in the four days the public health profession is in convention. The delegates are drawn from every state in the Union, from Canada, Cuba and Mexico and from every branch of public health practice. This makes necessary many individual meetings of the Association's ten sections—Health Officers, Laboratory, Vital Statistics, Public Health Engineering, Industrial Hygiene, Food and Nutrition, Child Hygiene, Public Health Education, Public Health Nursing and Epidemiology—where rock-bottom topics of interest to specialists alone are talked about, and in addition, sessions involving two or more Sections where subjects of broader import cut across the lines of the Section organization. A number of symposia will bring together three

and four of these divisions on such subjects as The Phosphatase Test in the Control of Milk Pasteurization; The Use of Biological Products; Water and Sewage; Frozen Desserts; Typhoid Fever; Pertussis; Nutritional Problems; Industrial Hygiene. Included among the speakers are

such nationally known leaders as Dr. Thomas Parran, Dr. Arthur McCormack, Dr. Abel Wolman, Dr. E. V. McCollum, Dr. Robert S. Breed, Dr. Elliott S. Robinson, Professor C. E. A. Winslow, Dr. I. S. Falk, Dr. Haven Emerson, Dr. Nina Simmonds, Dr. William F. Snow, Major Joel I. Con-

DRAINAGE OF THE ENTIRE BILIARY TREE

The Aim of Therapy in Biliary Tract Disease

Decholin—c. p. dehydrocholic (triketocholanic) acid—is of recognized merit in affections of the hepatobiliary mechanism. Acting directly upon the liver, it increases bile secretion as much as 200 per cent; at the same time, it markedly augments cholecystic evacuation. It is a means of establishing drainage from the entire biliary tree, thus aiding in the removal of inspissated, stagnant bile and nidi of infection, and

lessening the absorption of toxic metabolites. In the hands of many of America's outstanding internists Decholin is the medication of choice in chronic cholecystitis, hepatitis of toxic origin, non-calculous cholangitis, and biliary stasis. There is only one contraindication: complete obstruction of the common or the hepatic duct.

Second edition of the brochure "Biliary Tract Disturbances" sent to physicians on request.

EUSTERMAN, GEORGE B.

Chronic, Benign and Small Malignant Ulcerative Lesions of the Stomach: Factors Helpful in the Differential Diagnosis. Radiologic Review, 60:151-156, July, 1938.

In considering the differential diagnosis of small ulcerative lesions of the stomach the author discusses the significance of the roentgenologic findings, gastroscopy, symptoms, age, sex and time of onset, gastric analysis and results of treatment.

The roentgenologic examination, when carried out by a well-trained and experienced roentgenologist, is considered the most valuable single diagnostic agent.

Gastroscopy is of limited value in the diagnosis of early lesions as it is difficult for a diagnosis to be made even on close inspection of the resected specimen. It is only by histologic examination that successful differential diagnosis is possible.

The significance of sex, age, and time of onset is not such as to add materially in the differential diagnosis of benign and malignant lesions.

As regards gastric analysis, mean values for gastric acidity are of little help in differentiating malignant and benign lesions, however the extremes, such as achlorhydria or hyperacidity are of relative value in making the diagnosis.

Progress of the lesion under treatment as determined by repeated observations gives valuable information as to the type of lesion present.

Two charts are included listing the differential diagnostic features of carcinomatous and benign gastric ulcer.

AHLQUIST, RICHARD E.

Stones in the Common Bile Duct. Northwest Med., 37:213-217, July, 1938.

The frequency with which stones in the common duct occur without jaundice has not been sufficiently emphasized. Also, the percentage of cases in which stones in the common duct are overlooked at the time of operation on the gall bladder is too high. The general condition of jaundiced patients can be much improved during the preoperative period by the use of a diet high in carbohydrates, adequate fluid intake supplemented by glucose solution intravenously, calcium chloride solution intravenously and blood transfusions.

MILK FACTS

The dairy industry's importance to the national economic system is graphically visualized in the new MILK FACTS booklet issued by the Milk Industry Foundation.

Charts show that the United States is one of the ranking nations in the consumption of dairy products. With per capita consumption of fluid milk at 153 quarts a year, America tops all other countries except Switzerland with 232 quarts.

Annual per capita milk consumption in quarts for other nations is: Denmark, 144; Czechoslovakia, 136; Netherlands, 120; New Zealand, 112; Great Britain, France and Germany, 92; Australia, 88; Belgium, 68 and Italy, 28.

"Milk, in one form or another, comprises over 25 per cent of the 1,500-odd pounds of food used each year by the average American," says the booklet. "It requires about 10½ quarts of milk to make a pound of butter and 4½ quarts to make a pound of cheese. Approximately 350 million new milk bottles are purchased annually.

The booklet contains pictorial charts and figures showing the importance of the milk industry to the country's economic picture. Diagrammatic charts illustrate how the United States utilizes its milk supply of some 48,777,000,000 quarts of milk a year.

Fluid or fresh milk, which provides the farmer's highest cash return, accounts for 29.2 per cent of the country's yearly production. Creamery butter takes 31.6 per cent, farm butter—10.5 per cent, while 12.1 per cent of the milk is used on farms where produced. In making cheese 5.9 per cent of the total milk is used; ice cream—2.3 per cent and canned milks—4.3 per cent, according to charts.

Another chart shows a breakdown of the distributor's milk dollar based on recent certified accountants' figures prepared for the New York legislature. This shows that 44.03 per cent of the dollar goes to dairy farmers for milk; 26.16 per cent to labor; 8.75 per cent for supplies—bottles, cases, trucking, etc.; taxes—2.24 per cent; depreciation—2.40 per cent; profits—2.98 per cent; salaries—less than ¼ of 1 per cent.

"Within less than fifty years," says the booklet, "the production and utilization of milk have so increased in this country that today we are the greatest of dairy nations.

"Milk is our most widely used food, the farmer's largest source of cash income and the basis of an industry which for service and volume has few equals.

"Basic data about the nation's milk supply, the producers and the cows which create the supply, the distributors whose safeguards and efficiency have made wide usage possible and the consumers of this 'most nearly perfect food' are of wide interest.

"Around 25 million cows are milked daily on three quarters of the nation's six million farms—more than 45 million quarts of milk are delivered to homes and stores. Milk, cheese, butter, ice cream and other dairy products create an estimated annual output of 3½ billion dollars.

"The statistical background for this

Relief for the Arthritic

Salici-Vess

*Salicylate, Iodide
with Buffers, Effervescence*

For combined safety and effectiveness in antirheumatic medication. Incorporates two standard medicaments in the convenient, pleasant form of an effervescent tablet.

THE FORMULA:

Each tablet contains

Sodium Salicylate... 7½ grs.

Sodium Iodide... 1 gr.

Citric Acid... 17 grs.

Sodium Bicarbonate 25 grs.

The buffered alkalis. sodium

citrate and sodium bicarbonate in Salici-Vess not only enhance the therapeutic effectiveness but reduce toxicity to a minimum.

Note quick relief from pain and muscle spasm following the use of Salici-Vess. Tubes of 30.

Also available—Aspirin-Vess (aspirin with alkali buffers); and Alka-Vess (for safe alkalization).

RECENT ADVANCES IN THE SCIENCE OF NUTRITION

II. Newer Knowledge of the P-P Factor and the Control of Endemic Pellagra

● The years since 1932, when the P-P factor was known variously as vitamin B₂ or G, have been especially marked by contributions to our knowledge of the anti-pellagic vitamin. Considerable progress has also been made in the treatment of human pellagra as well as in the control of the disease. It might be of interest to review briefly a few of the outstanding developments in this field.

The P-P factor is now accepted as being closely related chemically to nicotinic acid if, indeed, it is not identical with that compound (1). Nicotinic acid has been used successfully in the treatment of human pellagra (2) and there is evidence to support the belief that the P-P factor is intimately associated with essential enzyme reactions in the body (3). A laboratory test has been devised for the early clinical detection of pellagra (4) and there is today better agreement as to the basic dietary requirements for the management of florid pellagra (1).

While the situation as regards endemic pellagra has, in general, shown improvement during recent years, an occasional report indicates that endemic pellagra still constitutes a major medical problem in some localities (5). Authorities agree that the old adage relating to an ounce of prevention being the equal of a pound of cure applies particularly well in the case of pellagra. Consequently, in specific regions of this country certain control measures have been advocated in an endeavor to bring this deficiency disease under permanent control. The most promising of these measures are

the issuance of yeast rations and popular education to the desirability of home production of foods rich in the P-P factor, especially during late winter and early spring. The problem of permanent control of pellagra has been clearly and briefly defined as follows:

"The prevention of endemic pellagra is simple in theory but difficult in practice. If every normal person received enough of the foods containing the pellagra-preventive vitamin there would be no endemic pellagra.—Permanent control can be obtained only by bringing about permanent changes in dietary habits" (1).

The correction of those long-standing dietary malpractices which are responsible for pellagra is certain to be brought about only slowly. The concerted and sustained efforts of all agencies concerned with public health will be required, not only to insure observance of the control measures described above, but also to educate the potential pellagrin to the necessity of a varied diet of protective foods.

Commercially, canned foods may play an important part in the current program designed to bring pellagra under control. Several hundred varieties of canned foods are readily available on every American market at all seasons of the year. Judicious inclusion in the diet of those foods known to be important carriers of the anti-pellagic factor (1) should materially assist in effecting permanent control of endemic pellagra in America.

vast industry of wide ramifications should lead to a clearer understanding of milk economies."

NEW MEASURING ROD FOR COMMUNITY HEALTH SERVICES

The American Public Health Association has today issued an APPRAISAL FORM FOR LOCAL HEALTH WORK. The present 200 page document is the result of studies in measuring community needs and community health activities by committees of the Association which have

been continuously engaged in this work for eighteen years.

The Appraisal Form is primarily a measuring rod for community health services. Through the use of a carefully arranged survey schedule the principal health problems of the community are brought to light and defined. The program of community health service in the several fields is analyzed against this background of social and health conditions. The health services as performed are studied in relation to the need with the result that the relative adequacy

of public health work is judged with some consideration of the magnitude and type of local problems.

Heretofore the Association has issued separate schedules for urban and rural work. Advances in rural health practice in the last few years, however, have been so great that the Association believes that issuing separate schedules for the measurement of urban and rural health service tends to accentuate the differences in practice which are rapidly disappearing.

The Appraisal Form is divided into three major sections: a survey schedule for studying a community's health facilities, a schedule for appraising the local health activities, and a list of significant health indices. The Association urges the use of the Appraisal Form by health workers and communities to evaluate periodically and impersonally their public health programs and determine the fields in which change of emphasis may be needed for more effective work.

CORWIN, WARREN C.

Experimental Hypercholesteremia in Dogs. Arch. Path., 26-2, 456, Aug., 1938.

The author takes up again the question of experimental arteriosclerosis in rabbits and guinea pigs due to excess feeding of cholesterol and the fact that it has not thus far been produced in other experimental animals; notably, in cats, dogs, foxes and monkeys.

In order to find out whether a constant hypercholesteremia could be produced in dogs and thereby render this animal a suitable subject for the further study of experimental cholesterol arteriosclerosis, the author conducted experiments on adult dogs in series of varying dietary conditions. First the limits of the cholesterol content of the blood of dogs on a "standard diet" were determined as 185 to 285 mg. per 100 cubic centimeter of blood, and of dogs fed a "kennel diet" as 155 to 240 mg.

Briefly the experimental results can be summarized as follows:

Dogs fed a high fat diet, the fat consisting of 5 to 10 gm. of lard per kilogram of body weight, showed slight but variable increases of the blood cholesterol. Dogs are naturally intolerant to high fat diets and frequently vomit their meals. This fact may have had some influence on the results.

Dogs on a high fat diet plus 3 gm. solid cholesterol in a capsule either with or without sodium cholate, gave the same indifferent results as seen in group 1.

Dogs on a high fat diet to which 10 to 15 gm. of lecithin of adrenal origin was added daily showed a blood

Phillips' Milk of Magnesia
(antacid-laxative)

WHEN YOU RECOMMEND GELATINE

in the diet, be sure it is

KNOX PLAIN SPARKLING GELATINE

(U. S. P.)

In order to clear up any confusion that may exist,
we indicate here the difference between a plain
gelatine and a ready-flavored gelatine dessert.

KNOX SPARKLING GELATINE	READY-FLAVORED GELATINE DESSERTS
All 100% gelatine.	Just enough gelatine to make them jell.
Absolutely no sugar.	85% sugar average.
No flavoring. • No coloring. • Just gelatine.	Contain flavoring and coloring matter.
pH about 6.0.	pH highly variable.
Protein 85%.	Protein 10 to 12%.
Knox Gelatine blends well with practically any food.	Almost solely a dessert not readily mixable with other foods.
Practical for a great number of diets which includes—diabetes, acute gastric ulcer, convalescence, anorexic, tubercular, etc.	Usually contraindicated in diabetic, gastric ulcer and other diets.

cholesterol of over 600 mg. per 100 cubic centimeter; and when cholesterol and sodium choline were added in addition the cholesterol values ran to a high of 940 mg.

A second series of experiments under varying dietary conditions corroborated in the main the results of the first experiments. It became evident that a high fat diet is not essential for the development of hypercholesteremia in the dog, and that solid cholesterol added to the diet did not materially alter the results. When lecithin alone was added to either the standard diet or to the kennel diet, elevation of the blood cholesterol took place. When it was added to a high

fat diet it produced a marked hypercholesteremia. This elevation in cholesterol content consisted both of free cholesterol and cholesterol esters.

The experiments were not carried long enough to determine whether arterial changes might occur or not.

N. W. Jones, Portland.

SIMONDS, J. P.

Mode of Origin of Experimental Gastric Ulcer Induced by Cinchophen. Arch. Path., 26-1, 44, July, 1938.

The author reviews the literature on experimental peptic ulcer and concludes from it that in most animals

the gastric mucosa is a very sensitive structure easily injured by a great variety of unrelated agents and that chronic ulcers probably result from acute lesions as a consequence of (a) general nutritional or metabolic disturbances, (b) local functional derangements, (c) continued action of the causative agent or (d) mechanical factors determined by the anatomic location of the acute lesion.

In order to determine if possible the mechanism by which ulcers formed, the author studied the histological changes found in the stomach and duodenum of some fifty dogs and cats which had been fed "old" cinchophen for periods of time from twenty-four hours to over three weeks. The lesions observed in all had as a common characteristic an acute gastritis. This was usually focal and occurred in different forms: (1) edema of a single, or several adjacent, villi; (2) diffuse infiltration of the villi or mucosa with plasma cells and lymphocytes; (3) superficial erosions, sometimes of a single villus; (4) focal accumulations of polymorphonuclear leucocytes above the muscularis mucosae often with liquefactive necrosis; (5) fistula-like channels from these areas to the surface, and (6) large deep ulcers, at times perforated. These lesions were nearly always located in the pylorus and first part of the duodenum.

Hyperacidity played no part in the formation of cinchophen ulcers. As the gastritis always preceded the formation of the ulcer in these instances, the author concludes it must have been an important factor in its causation.

N. W. Jones, Portland.

The most convenient and pleasant method of administering

Gastric Hydrochloric Acid

GLUTAN H-C-L

Indications. The literature shows GLUTAN H-C-L (Glutamic Acid Hydrochloride) to be a superior source of free hydrochloric acid in the treatment of gastric achlorhydria, hypochlorhydria, nervous anorexia, and in secondary anemia requiring a high protein diet, or whenever it is necessary to supplement or replace gastric hydrochloric acid.

Advantages. GLUTAN H-C-L is replacing the old methods of administering hydrochloric acid because

No unpleasant taste.

No sipping through a glass tube.

No irritation of the esophagus or decalcification of the teeth.

Put up in capsules which may be carried in purse, handbag or pocket—patients appreciate this convenience factor.

Contains glutamic acid, a centuries old condiment acting with hydrochloric acid the two produce a sense of well being after eating that is novel to patients who have long suffered from anorexia due to hypochlorhydria.

Supplied. GLUTAN H-C-L is put up in capsules, each of which is approximately equivalent to 10 minims of diluted hydrochloric acid U.S.P.

Bottles of 100, 500, and 1000 capsules.

Fill in and mail the attached coupon for a clinical sample and descriptive literature.

ZOLLINGER, R., BRANCH, C. D. AND BAILEY, O. T.

Instrumental Dilatation of the Papilla of Vater. S. G. O., Vol. 66, No. 1, pp. 100-104, Jan., 1938.

Since the histologic structure of the papilla of Vater is approximately the same in the dog as it is in man, the authors studied the effects of instrumental dilatation of the papilla in dogs and drew reasonable conclusions applicable to man.

These studies suggest that damage may be done to the papilla of Vater by instrumental dilatation, such as hemorrhage and inflammation in the acute stages and scarring in the later stages. The end result here is a smaller opening than results from no dilatation at all after cholecystectomy. It appears that the diameter of the papilla, unless scarred, adjusts itself to pressures in the biliary tree within a short time (90 days) after cholecystectomy. Subsequent dilatations after cholecystectomy do not tend to increase the diameter of the papilla. Perfusion pressures in patients who

UNDIFFUSED SALINE SOLUTION **provides LIQUID BULK** **for Gentle Laxation**

The osmotic influence of Sal Hepatica assures sufficient unabsorbed liquid bulk to provide activation of peristaltic muscles. The intestinal tract is thoroughly, yet gently, lubricated and flushed for removal of waste.

ANTACID CHOLAGOGUE

The mineral alkalines of Sal Hepatica act to relieve gastric-hyperacidity by combating excessive acid. Cholagogic and choleretic propensities of Sal Hepatica aid digestion by increase of bile flow.

Sal Hepatica simulates the action of famous mineral spring waters. It makes a zestful, effervescent drink. Samples and literature available upon request.

SAL HEPATICA *Flushes the Intestinal Tract and Aids Nature to Combat Gastric Acidity*
BRISTOL-MYERS CO., 19-NN West 50th St., New York, N. Y.

have had extensive dilatations of the papilla were higher than those in patients whose ducts were not explored.

The authors believe that it is sufficient to determine the potency of the papilla rather than attempt to dilate it forcibly.

Five figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.

Lake (Brit. Med. Jour., 2:49, 1937) reviewed 320 cases of partial gastrectomy

carried out for the most part for ulcer. Of the 198 cases followed for more than two years there was an unsatisfactory result in only fifteen. The gross mortality was 9.5 per cent in the ulcer cases, 14.8 per cent in the cases of jejunal ulcer, and 14 per cent in the cases of carcinoma. When the ulcer was situated in the pyloric region, the mortality of the operation was but 5.3 per cent. The incidence of jejunal ulcer after partial gastrectomy was less than 2 per cent. No cases of postoperative macrocytic

anemia were observed, but a mild microcytic anemia was seen in a few of the patients after operation. The average duration of life after operation in the patients with carcinoma was 2.25 years.

In the London letter in the Journal of the A. M. A., August 6, 1938, page 549, there is a report of some work by MacGregor on the endocrine treatment of senile vaginitis. Even the gastro-enterologist sees many women after the menopause who complain bitterly of burning in the vagina with perhaps some leukorrhea and perhaps dyspareunia. MacGregor used estradiol benzoate which restored the atrophic vaginal epithelium to a more normal condition. It increased the vascularity of the tissues and promoted healing of areas in which there was a tendency to bleed after denudation of the mucosa. It also helped in restoring the normal vaginal flora. With a cessation of this treatment the vaginal epithelium reverted to its atrophic condition. The drug was given in dosages varying from 5 mg. twice a week to 10 mg. a day according to the severity of the condition and the response. Intramuscular injection was the best method of administration. Suppositories proved disappointing probably because the atrophic condition of the vaginal mucosa interfered with absorption. Suppositories might perhaps have been used with greater benefit after the first doses had improved the local conditions. As a result of treatment eight of the fifteen patients were completely cured and they have remained that way from fourteen to twenty-one months. Vaginal douching should apparently be stopped.

Years ago Whipple and his students showed that over-irradiation with roentgen rays would punch holes in the mucosa of the small bowel. Cathie (Am. J. Roentgenol. and Rnd. Therap., 39:895, 1938) reports two cases out of a series of 400 in which the patients were treated with irradiation for carcinoma of the uterine cervix. In these two cases the patients developed intractable diarrhea and died. At autopsy ulcerations of actinic origin were found throughout the small bowel. The diarrhea appeared during the second week of treatment when only about 1500 roentgens had been delivered. A good many of the other patients had a transient diarrhea which cleared up spontaneously. It is possible that the two patients who did not get well had an idiosyncrasy to irradiation.

TRI-CALSATE

THE BUFFERED NEUTRAL ANTACID

Tri-Calsate is clinically effective in the treatment of hyperchlorhydria, heartburn, gastric and duodenal ulcer with these advantages:

1. Neutralizes the HCl of the gastric content and desensitizes the pain producing mechanism.
2. There is no evolution of carbon dioxide during the reaction in the stomach, hence the distress from gastric distension and belching is eliminated.
3. It does not make the gastric contents alkaline.
4. An excess of calcium tribasic phosphate is excreted in the intestine without producing an alkalosis.
5. The probability of gastro-intestinal irritation is remote.
6. There is sufficient alkaline salt (sodium-citrate) present to assist the neutral antacid (tribasic calcium phosphate) in the desensitization of the pain producing mechanism.
7. It does not injure the kidneys.
8. It is palatable and convenient to take.

Available on prescription or direct in 4½ and 18 oz. bottles.

Write for trial package and literature

Bland Bulk and Water Balance with **MUCILOSE**

A regimen for control of certain types of Constipation

CONTROL of constipation involves two important factors: proper balance of the water content of the fecal mass and the restoration of normal peristalsis.

Mucilose fills both requirements, for its bland bulk initiates peristalsis without irritation, and its ability to hold water in the bowel assures proper fecal consistency.

Mucilose is a hemicellulose (vege-

table gum) prepared from the *Plantago loeflingii*. Administration of Mucilose should be accompanied by copious water intake, to take advantage of the hygroscopic properties of Mucilose, and insure proper hydration of the feces.

Available as Mucilose Flakes and Mucilose Granules, Mucilose is as easy to take as a breakfast food—insures patient cooperation throughout the period of treatment.

tensive resection of the stomach because of ulcer. In most patients the operation had been performed more than seven years previous to this study. In all cases about two-thirds of the stomach had been removed. Thirty-six of the forty patients had a normal red count and a normal hemoglobin reading. Only four had a blood picture of a microcytic anemia.

Petri and his co-workers (*Acta Med. Scand.*, 93:450, 1937) feel as many others do that pellagra cannot

be explained completely on the basis of an inadequate diet. They saw insane patients in whom pellagra developed in spite of adequate nourishment. They saw also a number of cases in which they felt that they could cure pellagra by the use of extracts made from gastric mucosa. They believe that these extracts have been helpful also in the relief of the polyneuritis associated with alcoholism.

In an interesting paper published

recently, Parsons, Plummer, Ewalt and Gaskill (*J. A. M. A.*, 110:1991-1993, 1938) reported on the incidence of peptic ulcer in patients with syphilis of the central nervous system. As a basis for their study they used records of 200 patients who had clear-cut signs of nervous syphilis. In this group, with an average age of forty-one years, the incidence of peptic ulcer was 10.5 per cent. In another group of 200 patients with an average age of thirty-nine years and ordinary latent syphilis, the incidence of ulcer was 1.5 per cent. One hundred patients averaging thirty-four years of age suffering with pulmonary tuberculosis had an incidence of 1 per cent, while among the general admissions to the hospital the incidence was 3 per cent. In a series of 100 patients with peptic ulcer the incidence of syphilis was 5 per cent.

Because of much evidence showing that disease of the brain tends to be associated with peptic ulcer, it seems probable that the high incidence of ulcer in cases of nervous syphilis is due not to the syphilis but to disease of the brain. The writers doubted if syphilis was the cause of the ulcer in these cases. They admitted that the incidence of peptic ulcer in their series of neurosyphilitics was higher than that reported by other clinicians, but that, of course, might easily be explained on the assumption that their colleagues had taken greater care in examining the stomach roentgenologically.

Lazarus (*Brit. Med. Jour.*, 2:1011, 1937) studied the vitamin C situation in patients with bleeding ulcers. He first measured the amount of cevitamic acid excreted in the urine during a preliminary control period during which the patients were given an adequate diet with extra iron. Patients were then given large amounts of cevitamic acid for four days. Interestingly, none of the patients responded with a significant increase in urinary excretion of the substance, and the impression was that they were not absorbing much of it. Of the twelve patients studied ten were thought to be suffering with vitamin C undernutrition and sub-clinical scurvy. In seven, this lack was thought to be severe. One difficulty with all these studies is that some observers are not yet satisfied with the accuracy of the methods used for determining vitamin C.

W. C. Alvarez, Rochester.

Perazzo (*Arch. Ital. d. Chir.*, 47: 163, 1937) studied graphically the intestinal motility of dogs shortly before and after giving intravenous injections of 15 or 20 cc. of a 20 per cent hypertonic solution of sodium chloride. The injection caused an in-

Choosing a Happy Medium . . .

EXICOL

(Oleic Acid and Bile Salts)

The most recent researches* again emphasize the marked fat-intolerance displayed by patients suffering from gall bladder disease, and the satisfactory therapeutic results on a low fat diet and bile salts. Contrary to recent advocates of high fat therapy, it is pointed out that overstimulation of the gall bladder, produced by such high fat diets is undesirable.

Exicol, containing a small quantity of fatty acid and bile salts, offers a solution to the controversial problem of biliary tract therapy. It is the most rational therapeutic agent in biliary disorders because—

1. It stimulates mild gall bladder contractions due to the fatty acid.
2. Increases bile secretion from 100 to 200% ** due to synergistic action of oleic acid and bile salts.
3. Makes high fat diets unnecessary.
4. Exicol is most effective as an aid in the treatment of chronic cholecystitis, biliary insufficiency and other non-surgical as well as post-surgical biliary tract disorders.

71 SETS OF TRIPLETS THRIVING ON PET MILK

— *its significance to
the gastro-enterologist*

Significant? Yes — for the reason that an infant, particularly the premature, or an adult with an ulcerated digestive system, requires a milk which furnishes optimum nourishment with a minimum tax on the digestive organs.

Both, of course, require the protection of a milk that is free, surely and completely free, from bacteria which may cause infection or have irritative effect — and since Pet Milk, which because of sterilization, is so safe and so easily digested that triplet

babies, usually premature and always digestively hypersensitive, will thrive on it — it is logically a highly suitable food for the adult with an ulceration of the intestinal tract.

Fresh whole milk concentrated to double strength, then sterilized, Pet Milk, undiluted, furnishes with complete safety and in easily digested form, twice the solids of ordinary milk. It is therefore conducive to early healing of ulcerated areas — and consequently of interest to the gastro-enterologist.

We will gladly send samples and literature on request.

OLEUM PERCOMORPHUM CAPSULES

for diets deficient in
VITAMINS A and D

Where there is an intolerance or an aversion to fats, such good sources of vitamin A as dairy products are studiously avoided by patients. Obesity, diabetic, pregnancy, and low-cholesterol diets especially tend to be deficient in vitamin A. Oleum Percomorphum Capsules offer a convenient and highly acceptable means of correcting this deficiency and also furnishing generous amounts of vitamin D. Each 10-drop capsule supplies not less than 13,300 A units and 1,850 D units (U.S.P.), the equivalent of more than 5 teaspoons of U.S.P. cod liver oil in natural vitamins.

MEAD JOHNSON & COMPANY
Evansville, Ind. U. S. A.

crease of intestinal tonus and an increase in the amplitude of the pendular movements. This occurred also after bilateral vagotomy. The effect was transitory, lasting from twenty to forty-five minutes. The intestine reacted to a second injection but not to a third one. The author thought that the effect was due to changes of osmotic pressure in the tissues of the intestinal wall. The injection of physiologic sodium chloride solution, or from 6 to 8 cc. of a 20 per cent hypertonic solution did not have any effect.

W. C. Alvarez, Rochester.

At the meeting of the Central Society for Clinical Research (reported in the J. A. M. A., 110:685, 1938) Moore and Arrowsmith reported that iron is transported in the blood stream as serum iron. A new technic has been evolved for the study of the absorption of the iron from the bowel, and it has been shown that following the oral administration of iron, from three to ten times the basal amount in the blood appears in the serum. The authors studied this response in normal persons and also in persons with a histamine-refractory achlorhydria. In the achlorhydric persons they studied the influence of giving iron with hydrochloric acid. When iron is injected directly into the blood stream, all this iron is present in the serum fraction. The authors also studied the disappearance of various types of iron from the blood stream after intravenous injection.

W. C. Alvarez, Rochester.

MAX, H.

The Extent and Character of Peptic Ulcer and Gastroduodenitis in Different Countries. S. G. O., Vol. 66, No. 3, pp. 666-667, March, 1938.

The author points out that geo-medical variations of certain diseases are well known. These variations he has seen within a short distance of 100 to 200 miles in Germany as pertains to the occurrence of gastritis associated with duodenal ulcer. That the same differences may be observed in this country is obvious, as he shows. This probably accounts for the great differences reported in the degree of associated gastritis with duodenal ulcer in this country and in central European areas.

Two cases of gastritis associated with duodenal ulcer are reported.

He concludes that chronic erosive gastritis is more common in certain parts of this country than was previously thought. What parts those are he does not know. He recognized the absence of prohibition as a possible pertinent factor.

Six figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.

A GAROL HAS HAD A PHYSICAL EXAMINATION

The x-ray says: "Look for uniform density throughout as evidence of soundness"—and Agarol is a thoroughly uniform emulsion that acts the same way with every dose.

The microscope says: "Look for the small uniform oil globules" as a sign of thorough emulsification of Agarol. It means stability, freedom from oiliness, ready miscibility with water, milk, fruit juices or any other liquid.

The pharmacist says: "If it pours freely, it is the sign of a good emulsion." And, indeed, Agarol is a good mineral oil emulsion that has thoroughly proved its value in the relief of acute constipation and in the treatment of habitual constipation.

Ask us for the proof. Descriptive folder and a liberal supply of Agarol is at your disposal, but please write for them on your letterhead.

*Agarol is available in 6, 10 and 16 ounce bottles.
The average adult dose is one tablespoonful.*

GASTRIC TISSUE JUICE EXTRACT ENZYMOL

*Proves of special service in the treatment of
pus cases*

ENZYMOL resolves necrotic tissue, exerts a reparative action, dissipates foul odors; a physiological, enzymic surface action. It does not invade healthy tissue; does not damage the skin.

It is made ready for use, simply by the addition of water. These are simply notes of clinical application during many years:

Abscess cavities	Diabetic gangrene
Antrum operation	After removal of tonsils
Sinus cases	After tooth extraction
Cornual ulcer	Cleansing mastoid
Carbuncle	Middle ear
Rectal fistula	Cervicitis

CONNOTATIONS

H. J. SIMS, M.D.
Denver, Colorado

Paul of Aegina is often credited with having first recognized lead colic; however, Nikander described lead colic and paralysis after injection of excessive amount of lead in writings which appeared in the second century, B.C. Citois describes in 1572 an epidemic of lead colic followed by paralysis. He clinically described the disease. His religious tendency was such that he classed it with other diseases as representative of the wrath of God. Musgrave described in 1703 the symptoms of Devonshire colic. He intimated that it resulted from the use of crude cider. Baker of England read a paper before the College of Physicians on the cause of Devonshire colic, proving that it was the result of lining the cider presses with lead.

The Siamese Twins, Chang and Eng, were born of Chinese parents in Siam, China. They died at the age of sixty-three in North Carolina. Their bodies were joined at a point midway between the umbilicus and ensiform cartilage through which the blood vessels of their liver communicated. They married sisters. Chang was the father of six children and Eng the father of five.

The origin of the term *coll* dates back to 1665, the time of Robert Hooke. He observed spaces in cork which reminded him of minute prisons. Malpighi made the same observation in 1675. Jacob Schleiden published a paper in 1838 in which he described and recognized the importance of the nucleus in cells. He further observed that the nucleus of plant cells represented the mother of new cells and named it the cytoblast. Purkinje first used the term *protoplasm* to describe the cell content. In 1856, Johann Sigismund published an article in which he emphasized the cell as a mass of protoplasm with a nucleus. Eight years later he discovered the prickly cells in stratified squamous epithelium.

The term *retrocolic*, or retroperitoneal appendix, had its inception by Treves who stated in 1885 that the usual position for the appendix was behind the terminal end of the ileum, pointed toward the spleen.

In 1736, Garengnot probably described the first case of a true posterior vaginal hernia. In 1804, Sir Astley Cooper reported the second case. This type of tumor is not to be confused with a rectocele.

Robert Mayer of Germany, had occasion in 1840 to study the blood of people in tropical climates. In 1842, he prepared a paper on the forces of inorganic nature; it was refused publication. Because of his disappointments and adverse criticism, he attempted suicide in 1849. Two years later he was admitted to an insane asylum.

Dr. John Locke of Ohio, demonstrated in 1844 that the tick of a clock could be made to repeat itself over a long distance through a telegraphic media. In 1849, the government called him to Washington to construct the first electrochronograph.

During the time of Pliny, who lived 23-79 A.D., the head of an epileptic was shaved and the area bathed in oils, vinegar, and salt water. When all other methods failed, the drinking of warm blood from a slain gladiator was recommended.

Among the Greeks, epilepsy was known as the disease of Hercules. It is not known why this name was chosen. Some historians insist that Hercules suffered from the disease. Others believed epileptics exhibited superhuman strength during convulsive seizures, and again others accredited the disease to evil spirits.

Hippocrates spoke of the aura of epilepsy, although Pelops, 100 A.D., a pupil of Galen, is often credited with the first recognition. Apamea described the aura in 54 A.D.

In 543 A.D., Aetius of Armida, described lesions of the

Kalak with Sulfanilamide

*Palatable
Sparkling
Neutralizing*

IT HAS been observed that low concentrations of sulfanilamide appear to be bactericidal in infections of the genito-urinary tract if the urine is maintained at a pH of approximately 7.4.

Therefore use Kalak

- 1 *Before* sulfanilamide administration to establish the desired urinary pH.
- 2 *During* sulfanilamide administration to maintain urinary pH and to offset possibility of supervening acidosis.
- 3 *After* sulfanilamide therapy to promote diuresis and assist in elimination of any residual drug.

Kalak contains no sulphate and is not a laxative.

skin, now believed to have been eczema. Willan divided eczema into four classes. Fox of England, differentiated between impetigo and eczema in the year 1864.

Ulcers, especially those occurring on the extremities, were commented upon by Wiseman in 1676. Ulcers were not considered harmful to the patient as it was believed that through ulcers poisonous humors escaped. Wiseman's treatise on ulcers described the advantages of laced stockings. In 1783, Underwood substituted flannel bandages for lincn. Else recommended thin sheets of lead moulded to the contour of the leg as a means of support. Bayton, an English surgeon, suggested the use of strips of plaster prepared by the addition of diachylon to resin. This was melted and applied while warm to strips of bandages. The strips were then wound spirally around the leg.

In 1886, Lawson Tait reported that he had done 139 consecutive ovariectomies without a death.

Previous to 1850, the only attempts made to correct exstrophy of the bladder were those in which mechanical devices were used. The first operation was described by Roux in 1852. Melton in 1854 and Ayres in 1859 borrowed the idea of Roux and used a quadrilateral flap of epidermis with its base attached and its margin sutured to the edge of the bladder.

Most of the information concerning the practice of medicine and surgery among the primitive Mexicans is derived from the writings of Spanish priests. Child-birth was the source of many superstitions. A woman dying in labor was subjected to almost complete mutilation before the body was recovered by relatives. Each portion of the body was believed to be an astrological charm or symbol which would benefit the possessor by exerting magical or occult influence. Many rules were given to the expectant mother. She was cautioned not to expose herself to the rays of the sun and not to chew chicle as the child might

sicken. Any desire on the part of the mother to eat unusual foods must be ignored as food taken by the mother was imparted to the fetus.

Ephraim McDowell, one of the successful pioneers in abdominal surgery, for years had no diploma. He finally received his medical degree in 1825 from the University of Maryland.

CONNOTATIONS

vagina. This fact is attested by the directions and method of performing a caesarean section on the dying mother. The mouth of the uterus was held open the moment the patient took her last breath. For stimulation of labor pains the patient inhaled hellebore and ground pepper to induce sneezing.

Legg, in 1910, described the symptoms and roentgen ray findings of a condition now known as "osteochondritis deformans." Perthes, in 1913, gave the disease its present name and differentiated it from juvenile arthritis and tuberculosis.

In 1517, Hans von Gessdorf published a text-book on surgery. He describes himself as a citizen and wound treater of Strassburg. He gives the first illustration of amputation. The patient is seated in a chair. Narcosis was induced by opium. A cord was passed around the leg both above and below the proposed site of amputation. No effort was made to ligate blood vessels. Caustic plasters and the cautery was used to check hemorrhage. The stump was enclosed in the bladder of a bull, ox or hog. He aroused his patients by inhalation of vinegar. He also illustrates a trivalve vaginal speculum. The instrument represents some improvement over a similar one depicted in a text-book of surgery written by Jerome in 1497.

Huneyowski, in 1789, probably recorded the first instance of lateral cervical fistulae.

Mestiver, in 1759, reported a pertyphlitic abscess due to the presence of a needle in the appendix.

Lauger-Villermet described appendicitis gangrenosa in 1824.

The first illustrated book on surgery printed in the English language was by Jerome in 1525.

Pare, in 1522, published his work on surgery. He condemned the use of boiled oil and the cautery to control

hemorrhage. He was unable to obtain boiled oil on a special occasion and substituted a mixture of oil of roses, yolk of eggs and turpentine. His condemnation was in part altruistic.

Richter, in 1762, first suggested the advisability of opening and draining the peritoneal cavity in the presence of general peritonitis. This suggestion was carried out in 1816, by Von Vreeken, in Paris. Sixty years later Kaiser, of Freiburg, was able to collect fifteen cases operated upon.

The first operation undertaken in a known case of perforating ulcer following typhoid fever was carried out by Lucke of Strassburg, in 1887.

To Bollinger, a veterinary surgeon of Munich, is conceded the credit of having first (1877) discovered and described the "ray fungus" as constantly present in, and the cause of the disease called "lumpy jaw" in cattle. Perroncito and Rivolta, Italians, of Pisa, claim to have discovered the fungus in 1868. Harz, of Munich, suggested the name "actinomyces" from the Greek "aktis," a ray, and "mykes," a fungus. Isarel, in 1878, first described the disease in man. He did not differentiate the identity between that disease in man and cattle.

Gas cysts of the intestine were first observed by Colquet and Duvernay in 1825. Such cysts occasionally occur in healthy pigs.

It was fifty years after McDowell performed his first ovariectomy before the French School of Surgery admitted the merits of such a procedure.

Over fifty years ago, Dr. Alexander Goodell ironically remarked, "As the Angels, according to the Schoolmen of the Middle Ages, fly from point to point, without traversing the intervening distance, so, with like swiftness the physician of the present day jumps from any distinctly female ache to an ovarian conclusion."

For Convalescence

After any illness, when increased fluid intake of an alkaline nature is indicated, prescribe the real French Vichy, *Vichy Celestins*. It helps speed the journey back to health.

Early Cancer of the Stomach and its Clinical Significance*

By

WILLIAM CARPENTER MACCARTY, Sr., M.D.
ROCHESTER, MINNESOTA

IN 1827, Bright published his "Memoirs on Abdominal Tumors." He described no cancers of the stomach. In 1894, Osler also reported his experience with abdominal tumors and recorded twenty-four tumors of the stomach; all were large; all the patients were in the last stages of the disease; and all were treated merely palliatively; only one was submitted to surgery and that one died. In 1900, Osler and McCrae reported 150 cancers of the stomach; all were large; all the patients were in the late stages of the disease; and all of them were treated palliatively; only nine were operated upon; six of the nine were explored and

ever seen an early cancer of the stomach; such gastric cancers do not kill their hosts. Any opinions upon the origin of gastric cancer were purely speculative. Not until the operative surgeon began the exploration of living patients was it possible, and probable, for any one to see the early stages of cancer the profession hoped to see. For many years it was only the rare physician who permitted his cancer patient to see the surgeon; the great majority of cancers was hopeless even in the surgeon's hands; only rarely was he able to resect a portion of the stomach. All cancers of that organ were large and as such they really had the text-

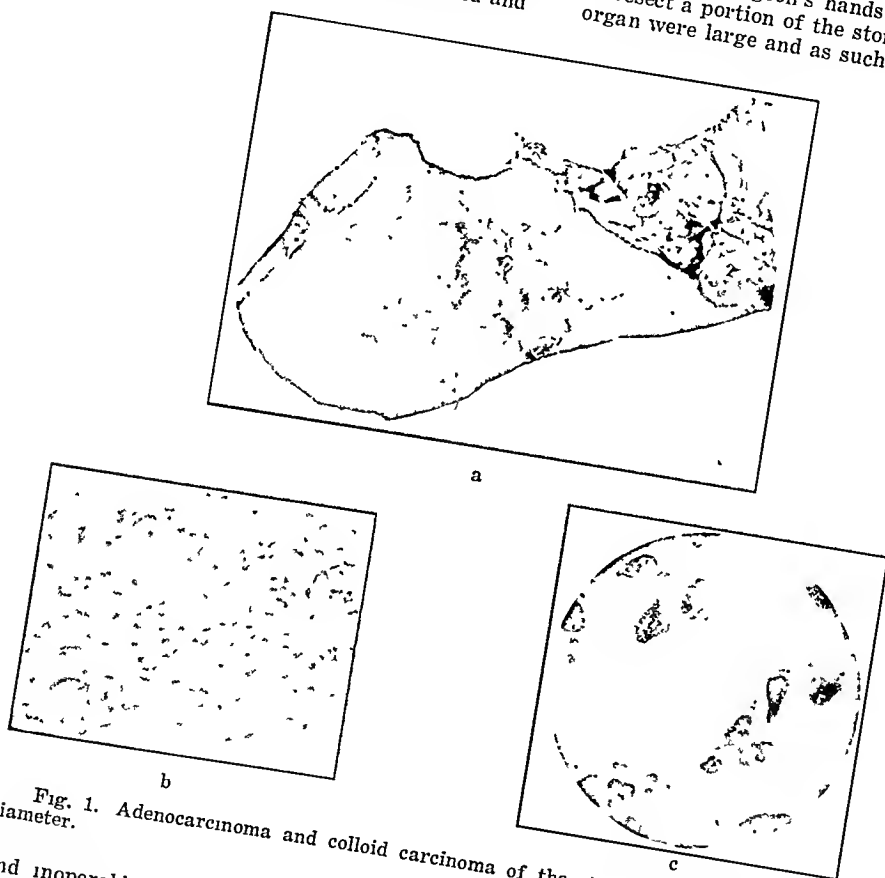

Fig. 1. Adenocarcinoma and colloid carcinoma of the stomach; ulcer 1.5 cm. in diameter.

the condition found inoperable; three of these died and the fate of the other three was not mentioned; one of the remaining three underwent gastro-enterostomy and died, one had a gastrostomy and died, and from the other a growth was removed but the patient died.

Up to 1907, or a few years later, no pathologist had

book signs and symptoms. Then came the roentgenologist beginning his gastric work in the second decade of this century; he visualized the stomach without surgical exploration. Some roentgenologists thought they could differentiate benign ulcers from cancer but the surgical pathologist showed them that in many cases that was impossible. As surgical technique improved, as the immediate operative mortality

*Read before the meeting of the American Gastro-Enterological Association, Atlantic City, New Jersey, May 2, 1938

Fig. 2. Adenocarcinoma and colloid carcinoma of the stomach; ulcer 2 cm. in diameter.

became less, and as the roentgenological technique got better, physicians became more willing to submit their epigastric patients to roentgenoscopy and surgical exploration. The surgical pathologist—not the post-mortem pathologist—began to look for small cancers. The surgeon resected some ulcers that were not cancer but neither the physician, roentgenologist nor the surgeon knew these ulcers were not cancer. Such specimens came to the surgical pathologist and some were small cancers.

Today I wish to tell you about 128 small gastric cancers. My first studies on gastric ulcer and cancer were begun in 1907. In 1918 I began the systematic measurement of all gastric cancers. From 1918 to 1931, inclusive, I measured 1568 resected gastric specimens: The average size was 6.1 cm. in diameter and 53 per cent had lymph nodal involvement; six per cent were the size of a quarter (2.5 cm.) or smaller.

From 1931 to 1937, inclusive, I have measured 410 specimens: the average size and percentage of those with lymph nodal involvement are approximately the same as in the earlier series. The frequency of cancers the size of a quarter or smaller has risen from 6 to 9.7 per cent; in 1936 the percentage was 21. In each year of the last six, the percentage was larger than the average for the period between 1918 and 1931.

In the whole series from 1918 to 1937, there were 1978 resected gastric cancers, 123 of which were relatively small cancers (2.5 cm. in diameter or smaller). The questions arise: How were these diagnosed? Did they have pathognomonic signs or symptoms of cancer? Throughout the 128 clinical histories one finds such terms or expressions as pain (dull or sharp,

sudden or burning), weakness, tired feeling, nausea, vomiting, flatulence, bloating, some cruetation, feeling of fullness, indigestion, stomach trouble and periodicity of symptoms. Contrary to the textbook pictures of gastric cancers these cases showed a general absence of such features as emaciation, palpable tumor, anasarca, accessory nodules, cachexia, pallor, edema of the legs, hematemesis, tarry stools and even loss of weight greater than might be explained by a restricted diet. Strangely, also, gastric acidity was high rather than low and the hemoglobin records were normal in the majority of the cases. None of the signs, symptoms, or laboratory findings were pathognomonic of cancer. Such signs and symptoms may be found when no cancer is present, as in simple gastric ulcer, duodenal ulcer, and, frequently, in association with cholecystitis and even appendicitis, brain tumor and syphilis.

Such varied symptoms are fairly common in any group of Americans. Certainly all who have the symptoms do not have cancer, but who has, and who has not, can be determined only by X-ray examinations, sometimes only by surgical exploration, and not infrequently only by microscopic examination. I presume that some of my critics will whisper disparagingly that I would X-ray or surgically explore every one with the slightest indigestion and would even advise that all ulcers should be removed. If they would only whisper a little louder we would see earlier and more curable cancers; at least 75 per cent of the cancers we now see would not be inoperable simply because the X-ray examinations were not made when they should have been. There may be economic reasons for not fluoroscoping or making films of all epigastric

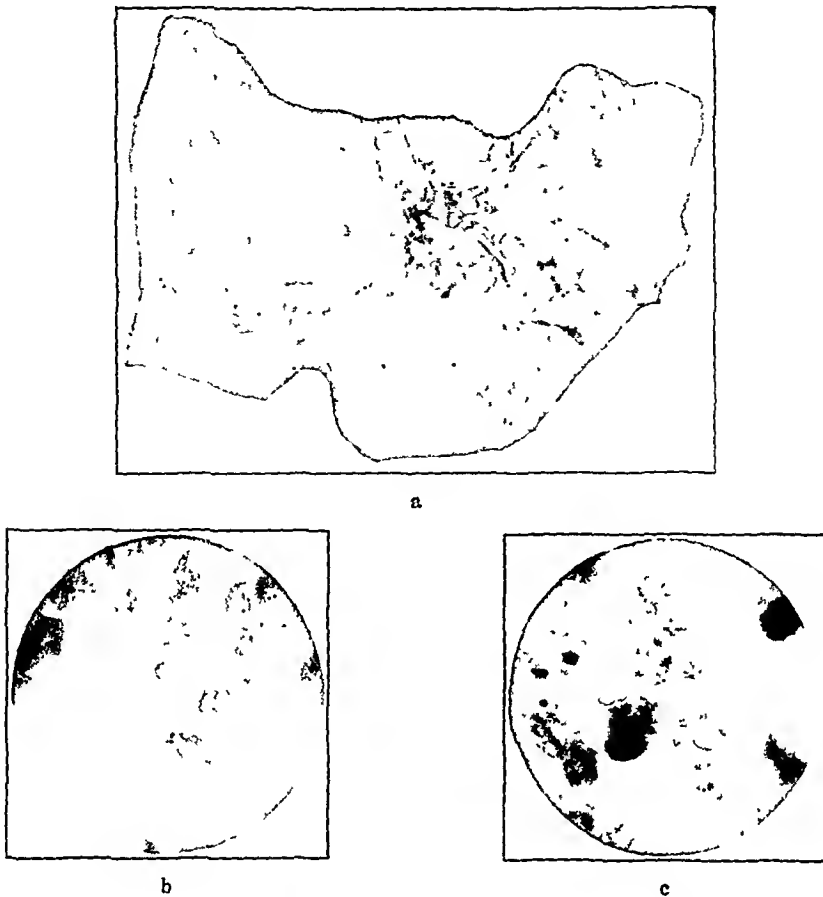

Fig. 3. Carcinoma of the stomach; ulcer 2.5 cm. in diameter.

disturbances but such reasons are rapidly becoming less and less valid. All of the 128 early cancers I am reporting were X-rayed, explored and excised; that is the only reason they were found.

Not until the practicing physician begins to apply, or have such methods applied, will he diagnose cancer of the stomach early. Early cancer has no textbook pathognomonic signs or symptoms and the sooner we appreciate this truth the sooner we shall handle the cancer problem intelligently and successfully.

I have presented this report merely to show that early diagnoses can be, and are being, made with increasing frequency—the frequency being parallel with frequency of thorough clinical study of every case of dyspepsia, indigestion and other mild epigastric disturbances that are now being handled too frequently as of slight significance. The medical profession must appreciate fully that early cancer cannot be found until suspicion, endoscopy, roentgenoscopy, biopsy, and surgical exploration are used very generally as diagnostic procedures.

DISCUSSION

DR. STANLEY P. REIMANN (Philadelphia, Pa.): Mr. Chairman, Ladies and Gentlemen: I begin by paying tribute to Dr. MacCarty for helping us uncover methods for early diagnosis in pathological specimens. I think his work, showing the difference in relative size of nucleolus to nucleus, and so forth, is worthy of great consideration. I always ask myself the question, what does he, what

do I, what do other pathologists try to do when they look at a microscopic specimen. We try to say what would have happened if the surgeon hadn't taken that specimen out. What would it have looked like a month from that time, two months, or three months from that time?

We try to turn ourselves into prophets and a prophet sometimes is not honored much in his own land. We can't tell sometimes because healing processes which take place even in cancer distort cells. They attempt to heal, but are frustrated. How can we tell what they would have done if the surgeon hadn't taken them out when he did?

The crux of the situation lies here: Are these cells distorted because their environment distorted them, or are they distorted because they never could have organized properly even if the environment had given them a chance?

This is the difference, gentlemen, between a cancer cell and a normal cell: The cancer cell cannot, even in this, that, or the other environment, organize into a proper structure, and we try to tell whether that cell or group of cells would have or not by looking at these very early microscopic pictures.

It is true enough when they have displayed their inability to organize by growing down through the submucosa, the muscularis, and the serosa, then we have no doubt, because they tell us, "We can't organize." If, on the other hand, they have not gone that far, are just very early, then it is up to us to guess what they would have done if that specimen had remained there.

These considerations are part and parcel of the dynamic approach to pathology. It is only part and parcel of the idea which can be expressed in any field in pathology.

Fig. 4. Carcinoma of the stomach; ulcer 2 cm. in diameter.

What was the picture two weeks ago, four weeks ago, six months ago? What would the picture have been two weeks later, four weeks later, six months later? We can't tell. All we can do is see the cells as of the instant when they were taken out and tossed into a fixative, formaldehyde, Sousa's, whatever fixative is used.

From that point of view, you will see that a great deal of the difficulties in nomenclature and classification—is this or is not cancer—is due to the one fact that we cannot be good prophets.

So far as regeneration is concerned, it occurs in the presence or absence of cancer. The stomach mucosa can regenerate very well. They tell me the sea cucumber, if you tickle or irritate it, will spit his stomach at you, and then sink to the bottom of the sea to grow a new stomach, which would be convenient for some of us. If we had a gastric ulcer, all we would have to do is spit it out and grow a new stomach. Unfortunately, we haven't that ability, but our stomachs do retain a considerable amount of power of regeneration.

Also, the same old question comes up of the influence of heredity and environment, and I was fortunate enough, and so was Dr. MacCarty, to hear Dr. Macklin this morning. I understand she was with you some three years ago. Some interesting new things have come out in her study, especially in relation to gastric carcinoma, and these she presented here. I wish I had time to rehearse one or two of her findings with you.

DR. WALTER L. PALMER (Chicago, Ill.): I have greatly enjoyed this paper. There is one question I should like to ask of the essayist. How many of the 126 patients with small cancers which were resected died subsequently of metastases? I am interested in the question as to

whether or not there are certain types of carcinoma which metastasize so early that we can scarcely hope to get them out before metastases have occurred.

Another question I wish to ask is with regard to healing in gastric carcinoma. Mention has been made several times today of the use of the decrease in size of the crater by X-ray as a differential criterion between benign and malignant ulcer. We have been very much interested in that. Last September I asked Prof. Hans Heinrich Berg if he had ever seen the crater of an ulcerating gastric carcinoma decrease in size. He replied that he had never seen convincing evidence of such a decrease. We have had two cases in which the crater disappeared or decreased in size roentgenologically, and yet the lesion was a carcinoma; however, it has been difficult for us to prove the point because at autopsy the pathologist said, "Well, I think this was originally a benign ulcer and carcinoma arose in the ulcer or elsewhere in the stomach." I would therefore appreciate a statement from Dr. MacCarty with regard to the amount of healing found pathologically in ulcerating gastric carcinomas.

DR. RUDOLF SCHINDLER (Chicago, Ill.): May I mention two considerations concerning early diagnosis of gastric cancer?

First: Evidently it is impossible to diagnose the first change in one or several cells to malignant cells. As long as no super-fine chemical reactions do indicate that there are malignant cells in the body and where they are, we have to depend upon the discovery of gross structural changes in the stomach by ventriculography, X-ray, and gastroscopy; however, in many cases even the early recognition of a malignant growth is of no avail because already as a so-called "early" stage, the tumor is too malignant to

permit complete cure. Therefore, we decided to call an early diagnosis only such diagnosis which would permit cure of long duration.

With this definition, the aspect of early diagnosis in gastric cancer would change entirely. Site, size, and even microscopic structure would become irrelevant; but we found that the diagnosis of the *macroscopic* type, as described by Borrmann is very useful. The Type I, polypoid, circumscribed tumor; and the Type II, localized ulcers with a sharply limited wall, give a good prognosis; Type III, partly infiltrating, malignant ulcers, have a very dubious prognosis; whereas the prognosis of all Type IV carcinomas, the diffuse, infiltrative ones, is not good, even if they are "early" diagnosed (early in the sense in which Dr. MacCarty uses the term).

In my experience the differentiation of these types is more easily made with the gastroscope than by X-ray.

The second remark: The pathologists (Ewing, Staemmler, Bertrand) think that 20 per cent to 50 per cent of all ulcers become malignant. The clinician who watches his patients having a gastric ulcer over a period of five to ten years, never, or almost never sees one of these ulcers turn malignant, if he makes the diagnosis with the gastroscope. If he were to rely only on clinical data or X-ray pictures, he would make mistakes, as was proved by the findings in three cases (but in only three cases) in a series of over 100 gastric cancers; in these three cases, mentioned by Dr. Palmer, the clinical and X-ray diagnosis was that of benign ulcer; the gastroscopic diagnosis, from the very first observation on, was that of a malignancy. These cases, without gastroscopy, would have been considered to be benign ulcers having turned malignant.

If about four per cent of all people die from gastric cancer, then also at least four per cent of all people suffering from gastric ulcer must die from gastric cancer. If the mortality from cancer would be less in this group, we would be forced to assume a protective power of the ulcer-bearing stomach against cancer. I am not willing as yet to admit such a strange power. I hope that in the future the gastroscoping clinicians also will be able to observe the growing of a tumor in at least 4 per cent of their ulcer patients.

I always have pointed out that it is easier to diagnose malignancy in the living tissue as seen through the gastroscope than in the bloodless specimen.

DR. JULIUS FRIEDENWALD (Baltimore, Md.): Dr. MacCarty has very ably discussed one of the most important as well as most difficult diagnostic problems in gastro-enterology.

It is well recognized that the familiar clinical picture of carcinoma of the stomach is that of the advanced disease. However, there are certain early clinical manifestations which may lead at least to a suspicion of this affection. These are:

1. The onset of indigestion in middle life in an individual in previously good health.

2. A supposedly benign disturbance of the stomach in which the characteristic symptoms are altered and become atypical.

3. Continuous absence of free hydrochloric acid in the gastric contents and persistence of blood in the stools.

4. Early evidence of obstruction at the pylorus or cardia.

If in addition to one or more of these, there are signs of gastric retention or roentgenological evidence suggestive of an ulcerating lesion of a type in which the niche, as has been pointed out by Kirklin, is larger than 2.5 cm. in diameter, the diagnosis should be considered as sufficiently established to warrant surgical intervention.

According to our experience, the roentgenological examination is the most valuable diagnostic procedure for determining the presence of carcinoma of the stomach.

In the diagnosis, the chronic ulcer which shows no tendency to heal and the presence of polypi should be regarded as pre-cancerous lesions.

Inasmuch as chronic gastritis is now considered by many as a precursor of cancer, it should likewise be regarded with suspicion when associated with other evidence of cancer.

One of the great difficulties in arriving at an early diagnosis is the fact that a malignant growth of the stomach may at times mimic the symptoms of a benign ulceration; and, in fact, in a small proportion of instances a chronic ulcer may insidiously undergo malignancy.

Again, a considerable number of carcinomatous ulcers occur before middle life, a fact which must be borne in mind in considering the possibility of a neoplasm.

When difficulty arises in differentiating between a chronic benign ulceration and a malignant lesion, I have found the method advocated by Dr. Jordan of the greatest value; that is, the patient is required to remain under close observation and treatment and if a rapid improvement ensues within several weeks, with a disappearance of occult blood in the stools, and especially with a gradual diminution in the size of the ulcer revealed by the X-ray, one can assume that the ulcer is of a benign character; however, if the ulceration shows no tendency to heal under these conditions, even though there is a general improvement in the symptoms, the diagnosis of malignancy must be considered.

Gastroscopy may likewise serve a useful purpose in determining the presence of an early growth.

When one realizes that there is not uncommonly a latent period which may extend over a considerable length of time before any evidence of this disease is manifested during which the growth may attain considerable proportions and the individual may still present the appearance of perfect health, it is easily conceivable how extremely difficult it may often become to arrive at an early diagnosis.

On this account it is important that roentgenological studies be made, if possible, of the digestive tract in the usual periodic health examinations in individuals of over forty years, and especially when affected with even mild chronic digestive symptoms.

As cancer of the stomach is most insidious in its early stages, a re-survey should be made at frequent short intervals in all instances of doubtful digestive disturbances, in order that a definite diagnosis may be reached as early as possible.

In conclusion, it is important, that if doubt as to nature of the gastric affection still remains, surgical exploration should be advised. It is only in this manner that we can hope to determine the presence of this disease at that stage when complete recovery can be expected as the result of surgical intervention.

DR. WILLIAM C. MACCARTY, Sr. (Rochester, Minn., closing the discussion): I wish I had time to talk about all of these discussions. Lots of things could be said, and I am going to summarize Dr. Reimann's discussion, I think, by asking myself a question: Does early cancer always kill? That is approximately what he has in mind. It is a question I have been deeply interested in myself, and I think it is very important not only for the pathologist but also for the clinician. I have the feeling that many of us develop the early stages of cancer and get well.

Dr. Palmer wanted to know how many died in the series. I can't tell him about the 128, but for a period of eleven years I studied part of this series, and 15 per cent of them were known to be dead in the eleven years, and theirs were smaller than a quarter. That may help a little. I am waiting to get the future records of the whole series. I never count anything that isn't definitely cancer that I can prove. I published those figures in *Jour. of Cancer Research*, Vol. xii, No. 1, March, 1928.

About crater decreasing, I feel quite certain that a crater of cancer can decrease under rest. There is a certain amount of inflammatory reaction associated with cancer; this disappears and the lesion becomes smaller.

I could show you records of patients alive after twelve years, in spite of the fact that all the lymph nodes on the specimen were involved.

There should be no great difference of opinion as to what Dr. Palmer and Dr. Schindler are doing with gastroscopy and what I would advise. I don't want anybody to think I am disagreeing with what they are talking about. They are dealing with acute things and with a lot of patients for the first time; many patients should be examined gastroscopically before they get in our hands and give us a chance to cut them out; I know Dr. Schindler feels some of his patients might be cancerous eventually. I am certain some ulcers diagnosed clinically and gastroscopically simple ulcer will be cancer. I would not be surprised if 15 per cent would ultimately turn out to be cancer.

He said something about the characteristics in the floor of a cancer. The early cancers of the stomach do not show in the floor. When a cancer gets in the floor, or the crater of an ulcer, it is very far advanced and is already in the

lymph nodes. The things I am talking about are in the border.

As to my friend, Dr. Friedenwald, I wish all the clinicians in the world were as good a clinician as he is. I often talk about that because so many of the young men today are being taught a lot of laboratory methods and become laboratory clinicians, but after you have seen things for a long while, you become a real clinician, and the changes in the clinical history which he mentioned are certainly very valuable.

I have an idea that early cancer sometimes gets well. Some lions and tigers are relatively benign and quite harmless but I would advise any one who expects to be near one to take along a very high-powered rifle. Expectant treatment in the possible presence of cancer is just about as dangerous as a twenty-two rifle in the presence of lions. I have seen enough small chronic gastric ulcers to make me just as suspicious of cancer as I would be of lions and tigers.

III. The Diagnosis of Colitis Associated With Virus of Lymphogranuloma Venereum by Bowel Antigen*†

By

MOSES PAULSON, M.D.‡

With the technical assistance of

BETTY KRAVETZ

BALTIMORE, MARYLAND

MORE than a decade ago, Frei pointed out that when bubo pus, due to the virus of lymphogranuloma venereum, is diluted 1-5 or 1-10 and inactivated, such an antigen will give a characteristic intradermal reaction in those who have been or are affected with this venereal disease. Such an antigen (inactivated bubo pus due to the virus of lymphogranuloma venereum) has become known as the Frei antigen, and the intradermal response to it, the Frei reaction. This immunologic phenomenon is regarded as highly specific.

In many, particularly the males, the disease may terminate as a bubo. In some, especially in women, the virus may descend the pelvic lymphatics and attack the bowel. The tendency is for the bowel process to result in a cicatrizing, fibrosing, stenosing lower rectum with an ulcerative colitis above the stricture. This is the clinical picture as it is usually known; it is the advanced stage of this disease. Not infrequently, however, the clinical picture is not typical: there is the pre-stricture stage and sometimes an ulcerative colitis which is not readily distinguishable from other forms of colitis. Besides, as will be pointed out, the Frei reaction has its limitations in diagnosis. In addition, it has appeared to me that not much greater progress can be expected in the etiology of the indeterminate diarrheas and dysenteries, colitis and enteritis with the present bacteriological and parasitological approaches.

In an attempt to clarify some of these problems, in 1936 I reported (1) intracutaneous responses comparable to positive Frei reactions, with colonic exudate from chronic ulcerative colitis cases with positive Frei reactions. The successful preparation of these bowel antigens was a fortuitous circumstance, and because of technical difficulties noted elsewhere (1, 3) control antigens were not obtainable. The significance of these cutaneous allergic responses, paralleling positive reactions with known active Frei antigens, suggested the presence of an inciting agent unlike a toxin, a specific bacterium or foreign protein, probably the virus of lymphogranuloma venereum or viruses within the intestine of man.

In 1937, improvements in technique due principally to the use of Azochloramid (2), an excellent synthetic bactericidal and bacteriostatic chlorine compound, it was possible to report (3) a dependable, although crude, method of antigen preparation. This resulted in a practical intradermal diagnostic method indicating the presence of the virus of lymphogranuloma venereum in the intestine and differentiating colitis associated with that virus.

This communication reports the securing of eight additional "bowel discharge antigens" and two "bowel (rectal) tissue antigens"* as well as seven control antigens from various sources. The bowel tissue antigens have not been presented by me before. A distinction is being made here between antigens prepared from blood, mucus, pus, bacteria and intestinal contents, grossly fecal-free, heretofore simply called "bowel antigen" and now designated as "Bowel Dis-

*From the Gastro-Intestinal Section (T. R. Brown, Chief) and Laboratories of the Medical Clinic of the Johns Hopkins Hospital and the Johns Hopkins School of Medicine.
†Associate in Medicine, Johns Hopkins University School of Medicine; Physician (Consultant in Digestive Diseases) to Diagnostic Clinic; and Assistant Visiting Physician, Johns Hopkins Hospital.
Presented before the American Gastro-Enterological Association at Atlantic City, N. J., on May 3, 1938.

*Thanks is due Mr. Frederick Berry Bang, a third year medical student in the Johns Hopkins University, who secured for me a specimen of bowel tissue for antigen preparation.

charge Antigen," and those prepared from the bowel substance itself, "Bowel Tissue Antigen." The use of this terminology is suggested not only to differentiate types and sources of bowel antigens but to distinguish them from the Frei antigen (inactivated bubo pus due to the virus of lymphogranuloma venereum) and its antigenic response (Frei reaction).

The data to be submitted further establishes, it is believed, the practicability, utility and importance of the method.

PROCEDURES

The method of preparing "bowel discharge antigen" under the previous designation of "bowel antigen" has already been described in detail (3). It is reprinted here for completeness.

I. BOWEL DISCHARGE ANTIGEN:

A. *Preparation of Patient.* Two enemas of physiologic solution of sodium chloride are given, one at bedtime and the other on the following morning a few hours before the rectosigmoidoscopic examination. The purpose is to prevent gross fecal contamination.

B. *Securing of Material.*

1. Devices employed:

(a) A rectosigmoidoscope 1 cm. (three-eighths inch) or 1.6 cm. (five-eighths inch) in diameter and 25 cm. (10 inches) in length is employed, depending on the presence and size of the stricture. An instrument smaller than 1 cm. in diameter does not allow adequate vision and satisfactory insertion of the aspirator. This aspirator is of metal and measures 35 cm. by 8 mm. These are sterilized by boiling. A suction apparatus is also needed.

(b) The receptacle is a glass tube, 15 cm. (6 inches) high by 2.5 cm. (1 inch) in diameter, containing fifteen glass beads. The rubber stopper, glass and rubber connections are sterilized in the autoclave.

2. *Method:* The material, which is usually mucopurulent, frequently bloody, but grossly free from fecal matter, is aspirated by suction into the glass tube containing beads. The prime object is to secure it undiluted and measurable in order to make accurate antigen dilutions; thus, to 1 cc. of the material, 10 cc. of a diluent (Azochloramid, to be referred to later) is added. This is called a 1 to 10 dilution. In most instances this is not possible, for either there is too little exudate or it is very tenacious, too thick or,

sometimes, not visible. Under such circumstances 5 cc. of the diluent is poured through the rectosigmoidoscope and then quickly aspirated.

Aspirated material is vigorously agitated so as to be well mixed and to be broken up into smaller particles.

Whenever dilution in vivo becomes necessary, the subsequent dilutions in vitro in the preparation of antigen become arbitrary, since standardization by weight or volume is impossible; however, the same criteria, to be noted, are employed throughout. Whenever the material is too thick to be readily drawn into a sterile calibrated 10 cc. pipet, it is treated as undiluted and to each cubic centimeter 9 cc. of the diluent is added. It is arbitrarily designated as a 1 in 10 dilution. Material of "medium" consistency is that which can be drawn into a sterile calibrated 10 cc. pipet with facility. Usually, from 3 cc. to 5 cc. of this material is obtained. The diluent is added to make a total volume of 10 cc.

Not infrequently, the aspirated material obtained after the addition of the azochloramid through the rectosigmoidoscope is very thin and translucent, contains little bowel exudate and is mostly diluent. In this case no further dilution is made.

It is to be emphasized that the dilutions are actually higher than indicated, since sodium sulphite and merthiolate—as will be noted—are added.

C. *Preparation of Antigen.* I have already reported the inability to demonstrate the presence of a reaction-producing substance either in filtered bubo pus, a portion of which when unfiltered produces a positive Frei reaction, or in filtered bowel material. Thus, the problem in the preparation of bowel antigen concerns itself with the destruction of bacteria without disturbance of the antigenic factor and with dilution of the material sufficient to decrease foreign protein, so as not to mask the intradermal reaction, and yet insufficient to eliminate for practical purposes the antigenic factor. Also, heating at 60° C. for two hours on one day and one hour on the following day, even in the presence of the bactericidal and bacteriostatic action of the antigen diluent—azochloramid—will not always result in complete bacterial destruction. A higher temperature at 80° C. for one hour is also employed, since I have learned that the antigenic

product in bubo pus due to venereal lymphogranuloma will withstand higher temperatures.

The heating is accomplished in the following manner so that at least one antigen will be obtained from a given patient suitable for use in the face of the difficulties referred to:

Equal portions of the material aspirated from the bowel through the rectosigmoidoscope, with or without the addition of 5 cc. of azochloramid, are placed in four sterile 5 or 10 cc. No. 12 army vaccine vials.

Vial A: The contents are diluted either 1 in 10 or 1 to 10 with azochloramid, as already indicated. The vial is sealed with a rubber stopper and collodion and heated in a water bath at 60° C. for two hours, left at room temperature over night and on the following day heated at 60° C. for one hour.

Vial B: The contents are identically diluted and sealed, but the vial is left at room temperature over night to insure the complete action of azochloramid, which is modified by the higher temperature of 80° C. for one hour to which the vial is submitted on the following day.

Vial C: The contents are diluted with half the amount of azochloramid used in vials A and B, and the vial is sealed and heated at 60° C. for two hours. Then, by means of a sterile needle and syringe, the other half of the diluent is added. This vial remains over night at room temperature and on the following day is heated at 60° C. for one hour. The purpose is to supply fresh bactericidal action on organisms surviving both the original supply of azochloramid and the first heating, while making the final dilution no higher than that of the previous antigens.

Vial D: The contents are diluted with half the amount of azochloramid used in vials A and B, and the vial is sealed and left at room temperature over night. Then it is heated at 80° C. for one hour, after which the remaining half of azochloramid is added.

Not infrequently, the material obtained through the rectosigmoidoscope after the necessary addition of 5 cc. of azochloramid is thin, translucent instead of opaque, contains little bowel exudate and is mostly diluent. Equal portions of this material—without further dilution—are placed in two vials. One is heated at 60° C. for two hours and for one hour the

following day. The other is left at room temperature and on the following day is heated at 80° C. for one hour.

In general, the thicker the fecal-free material, the greater is the likelihood of preparing a satisfactory antigen.

In order to dechlorinate the antigens to eliminate the irritating dermal properties and to avoid the carrying over of free chlorine to the sterility test medium, the following procedure is carried out: To azochloramid solution (1:1,666) equivalent to the amount in the vial to be dechlorinated, a sterile, fresh 10 per cent aqueous solution of sodium sulphite is added until the yellow color completely disappears. An equal amount of the sulphite is added to the antigen.

Sterility tests then follow: 0.1 cc. of antigen is placed in 5 cc. of infusion bouillon and incubated aerobically, and 0.1 cc. is inoculated in anaerobic cooked meat medium. The cultures are incubated for seven days. A deep blood agar pour plate is then inoculated with 1 cc. of infusion bouillon culture and incubated aerobically. An anaerobic plate is inoculated with an identical amount from the cooked meat culture, if it is not obviously contaminated, and incubated anaerobically. The plates are incubated for four days.

Merthiolate (1:10,000) is added to each vial immediately after the medium for sterility tests has been inoculated. Not until sterility tests are satisfactorily completed are antigens ready for use.

My experience has been that of the four antigens prepared as outlined in each case, at least one is satisfactory. It is to be reemphasized that this result can be consistently accomplished only by the avoidance of gross fecal contamination.

Although no differences have been noted with antigens heated at varying temperatures and for the durations noted, I have preferred to employ those prepared at 60° C. when obtainable.

II. BOWEL TISSUE ANTIGEN:

A. Preparation of fresh, unfixed tissue:

(1) The tissue is washed thoroughly in tap water and rinsed with 1:1666 solution of Azochloramid.

(2) To each gram (not more than 5.0 grams) 1.0 cc. of 1:1666 Azochloramid in physiologic salt solution

TABLE I CONTINUED

± indicates male and ♀ indicates female.

These figures represent single responses to separate antigens; no repetitious test with any antigen on the same patient has been recorded.

is added. It is macerated in a sterile mortar with a pestle and the supernatant fluid removed.

(3) To the residue, the same quantity and strength of Azochloramid, as above noted, was added. The tissue was further macerated and the supernatant fluid was added to that which had been removed previously.

(4) This turbid suspension was placed in a sterile No. 12 Army vaccine vial, sealed with a rubber stopper and collodion and heated in water bath at 60° C. for two hours on one day and for one hour the following day. Sterile precautions were observed throughout. Dechlorinization, sterility tests and addition of merthiolate followed identically as noted above in the preparation of bowel discharge antigen.

B. Preparation of Formalin—Fixed Tissue: (1) Tissue previously fixed in 10% formalin—not in excess of 1.5 grams was left in tap water overnight. (2) It was then rinsed with Azochloramid 1:1666 in physiologic solution of sodium chloride. (3) It was macerated in a sterile mortar with a pestle, and to each gram of tissue ten times the volume of Azochloramid of the strength noted above was added slowly. Thus, to 1.0 gram of tissue, 10 cc. of Azochloramid was used. The latter was added in small quantities during maceration and the resulting suspension was removed from time to time and placed in a sterile vial. The remaining procedures, checking the action of Azochloramid (dechlorinization), sterility tests and the addition of merthiolate for bacteriostatic purposes were identical with those described above.

THE DILUENT AZOCHLORAMID

I have found that Azochloramid destroys all types of intestinal bacteria, both aerobic and anaerobic, in tremendous numbers in dilutions which, on the addition of sodium sulphite, will give no intradermal reactions. It will not destroy the antigenic substance due to or associated with the virus of lymphogranuloma venereum. Its action will not be disturbed at 60° C. and can be checked immediately by the addition of sodium sulphite as noted. Its use made possible the dependable preparation of bowel discharge antigens—

for reasons already noted. (3) With fresh washed or fixed tissue as the material for the antigen, its use was mainly that of destroying possible air contaminants. As composed with physiologic solution of sodium chloride as the diluent, Azochloramid appeared to increase the likelihood of securing antigens free from viable bacteria. This new chlorine compound of unusual properties was introduced by F. C. Schmclkes in 1934. (2).

SOURCES AND TYPES OF ANTIGENS

Type I. Bowel discharge antigens from patients presenting a positive Frei reaction and ulcerative colitis without elephantiasis or vegetations which have been subdivided in the master chart (Table I) as A, those with stricture, and B, without stricture.

Type II. Bowel discharge antigens from a patient presenting a negative Frei reaction (to eight active human Frei antigens) and a colitis with the brunt of the involvement in the rectum, but without stricture.

Type III. Bowel tissue antigens from excised, strictured rectums of those with colitis and positive Frei reactions.

Type IV. Bowel discharge antigens from patients presenting a negative venereal lymphogranuloma history, a negative Frei reaction, with ulcerative colitis without stricture (controls).

Type V. Bowel tissue antigens from fresh, unfixed carcinomatous ileal and cecal tissue (control).

Type VI. Generative tract discharge antigens from three cases presenting negative Frei tests and leucorrhoea. In one the gonococcus was demonstrated; in the others the etiology was undetermined. No history of lymphogranuloma venereum or evidence of colitis was obtainable in this group (controls).

SUBJECTS ON WHOM ANTIGENS WERE TESTED

Intradermal reactions with these antigens were tested on colored and white men and women, with positive and negative Frei reactions, who were free from any active systemic disorder and organic gastrointestinal disease.

TABLE II
Intradermal responses to bowel and control antigens

Type of Antigen	All Intradermal Tests (257)

			Total	3.5%				0%

INTRADERMAL REACTIONS AND INTERPRETATIONS

One-tenth cc. of either type of bowel antigen is injected intradermally, as is the Frei antigen, several specimens of which are tested simultaneously on each patient for comparative purposes. The results are read at nine or ten days. A reaction with the Frei or either type of bowel antigen is considered positive only if its minimal dimension of induration or papule formation in any direction, usually the diameter, is at least 5 mm. Induration is found more often than papule formation with or without necrosis. Induration may extend beyond papule formation, and when this occurs it is included in the measurement. Erythema extending beyond induration and papule formation, or any skin scarification or pigmentation, is not considered in measurement. Induration and papule formation are the basis of measurement. Palpation and careful measurement rather than inspection are important factors in determining results. Experience is essential for proper interpretation, but this is readily acquired. Bowel antigens should be tested on at least three patients known to have a positive reaction to at least one satisfactory Frei antigen and three without any history or evidence of venereal lymphogranuloma and with a negative reaction to multiple Frei antigens. Both groups should be free from any active systemic disorder or any organic gastro-intestinal disease.

RESULTS — COMMENT

The master chart (Table I) is a tabulation of raw data secured by the use of seventeen test antigens of six already described types on forty-two patients totalling 267 intradermal tests. Table II and Table III

TABLE III

Positive responses to individual positive bowel antigens

Antigens	No. of Positive Frei Cases Tested	No. Positive	Per Cent Positive
1. Type IA (1)	10	4	40%
Type IA (2)	10	6	60%
Type IA (3)	7	7	100%
Type IA (4)	10	8	80%
Type IA (5)	8	4	50%
Type IA (6)	8	5	62.5%
2. Type IB (1)	11	10	99.9%
3. Type II (1)	5	3	60%
4. Type III (1)	5	2	40%
Type III (2)	5	3	60%

Positive bowel antigens previously reported

1	10	10	100%
2	10	10	100%
3	13	8	61.5%
4	5	5	100%
5	6	2	33.3%
6	6	4	66.6%
7	5	5	100%

are contractions of data derived from the master chart which are presented for further clarity and to point out the percentages of positive and falsely positive reactions.

Ten positive antigens were realized from ten suspected sources. It should be pointed out that this study is not a study of incidence; it is not a quantitative one. For the purpose of establishing bowel antigen as a diagnostic method, material for antigens was obtained from the most likely sources available. Negroes comprise the vast majority of our material source. They constitute a large portion of the hospital population here, are readily available, and for the most part very cooperative. Thus, it is not to be inferred that this disease is confined almost solely to negroes. The majority of cases reported by Mathewson (4) from San Francisco were among the whites. Few negroes live in Germany and in Scandinavia where the disease is not rare.

Reactions to positive bowel antigens (Types IA and IB, II and III) paralleled the positive Frei reactions in 66.6 per cent of instances (Table II). Reactions to individual antigens of this group varied as follows: Two were positive in 40 per cent of instances tested, one in 50 per cent, three in 60 per cent, one in 62.5 per cent, one in 80 per cent, one in 99.9 per cent and one in 100 per cent (Table III). There were no false positive reactions. In this connection, it is to be noted that individual human Frei antigens also vary in the percentage of positive responses in cases known to be positive to other Frei antigens (Table IV). These variations in bowel and Frei antigens may be due in part to quality and quantity of antigenic substance present and in part upon the individual response to a given "strain." Hence the necessity of using multiple Frei antigens and at least three cases known to be positive to the Frei antigen in testing bowel antigens. In the case of bowel discharge antigen, a "weak" strain may also mean a gradual disappearance of the virus from the seat of involvement: in 1936, the "McK" antigen (1) was positive in 100% of cases giving positive Frei reactions; six months later, with the clinical picture unchanged, another antigen was prepared which gave no responses in cases with positive and negative Frei reactions. A "weak" bowel antigen may also result from the dilution of the antigenic substance in vivo by blood, mucus, pus, bacteria, intestinal contents and sometimes by an accompanying dysentery. Control antigens, Types IV, V and VI averaged false positive reactions in 3.5 per cent of cases with positive Frei reactions. These control antigens gave no false positive reactions in those with negative Frei tests. It is to be emphasized that Type VI antigens (controls) were prepared from vaginal discharges from those with negative Frei tests.

False positive reactions have been markedly reduced in this series of seventeen antigens (Table I) as compared with other antigens previously reported (3). This is believed to be due (1) to the discarding of all bowel discharge evidencing gross fecal contamination in the slightest degree, and (2) to the use of skin test subjects free from any active systemic disease, particularly colitis.

The reasons for believing that a positive bowel antigen indicates the presence of lymphogranuloma venereum virus in the bowel of the person from whose intestinal material the antigen was prepared has been

discussed in detail elsewhere (1, 3). Recently, the following evidence in substantiation has been adduced: uninactivated bowel discharge from which a positive bowel antigen had been obtained was inoculated parenterally into a male dog. Five weeks later the dog tested with two Frei antigens gave positive reactions to both, and a negative reaction to a control antigen of inactivated bubo pus of a non-specific nature. Previous to the administration of the uninactivated bowel discharge, the dog had been negative to three active Frei antigens, one of which produced one of the two positive reactions referred to.* The accompanying photograph (Fig. 1) was taken at the end of ten days. The reactions were still positive at the end of two weeks.

Attention is directed to the results with bowel tissue antigens (Type III). The tissue when submitted for such preparation had already been fixed in formalin. Despite this, one antigen was positive in two of five cases with positive Frei reactions and the other in three of five. They were negative in four and three subjects respectively, with negative Frei reactions. Control antigens from unfixed cecal and ileal malignancy tissue were negative in subjects both with positive and negative Frei reactions. This points out the possibilities in and the desirability of the use of tissue antigen for diagnosis both ante and post mortem, especially since the histopathology is not universally regarded as pathognomonic (4).

TABLE IV

Positive responses to individual human active Frei antigens

Antigen No.	No. Positive Frei Cases Tested	No. Positive	Per Cent Positive
1	14	14	100%
2	11	9	81.8%
3	29	19	65.5%
4	42	35	83.3%
5	11	7	53.5%
6	17	15	94.1%
7	4	3	75%
8	5	5	100%
9	12	11	91.6%
10	10	5	50%
11	8	8	100%
12	15	14	93.3%
13	5	5	100%
14	8	6	75%
15	4	4	100%
16	8	6	75%

The further clinical significance of the use of bowel discharge and bowel tissue antigens does not rest principally on its use from cases presenting colitis, stricture, inguinal scar and positive Frei reaction. These are advanced states and are readily diagnosed. Rather, the importance of bowel antigen rests in the following:

(1) The limitation of the Frei reaction:

(a) Anergy. This is a well known immunologic phenomenon (5, 6). A number of lymphogranuloma venereum cases do not give positive Frei reactions with multiple active human antigens. This problem may not be troublesome where the case presents a typical clinical picture. However, this does not account for those cases presenting negative Frei reactions and clinical states less typical or indistinguishable from those brought about by other agents and in whom anergy can only be detected after a positive bowel antigen has been obtained. An example will suffice. A negress, negative to eight active human Frei antigens, presented a colitis without stricture, whose bowel discharge antigen (Type II) gave three positive re-

Fig. 1. Examples of intradermal reactions to bowel antigens. Colored male with positive Frei reaction with no active systemic or organic gastro-intestinal disease. Responses were read at 9 days. 1 is a positive reaction to positive bowel discharge antigen, Type IB. 2, 3 and 4 are positive reactions to positive bowel discharge antigens included in Type IA. 5 and 6 are negative responses to control tissue antigens, Type V. 7 is a positive reaction to a 1:5 dilution of active human Frei antigen. 8 is a negative response to a control bowel discharge antigen included in Type IV. 9 is a positive response to a positive generative tract (vaginal) discharge antigen (to be reported). 10 is a negative response to a control generative tract (vaginal) discharge included in Type VI.

*Thanks are due to Dr. Ferdinand C. Lee, Associate Professor of Surgery, Johns Hopkins University (in charge Surgical Hunterian Laboratory) for opportunities afforded to pursue this phase of the work.

Fig. 2. Positive reactions in a male dog with two active human Frei antigens at 10 days following the parenteral injection of unactivated bowel discharge from a patient from whom a positive bowel discharge antigen had been obtained. Prior to bowel discharge administration, the dog was negative to 3 active Frei antigens, one of which produced one of the two positive reactions shown. These positive reactions were as pronounced at 14 days. The control antigen consisting of inactivated bubo pus of non-specific origin from several human sources produced no reaction. This, it is believed, helps further to establish that the virus is present in material from which a positive bowel antigen is secured, and the skin response is brought about either by the inactivated virus or an associated product.

actions in five cases with positive Frei tests and no reactions in six cases with negative Frei tests (Table III).

(b) The Frei reaction may represent an antedated, healed or unrelated virus infection. A positive bowel antigen is a more specific, and a more direct diagnostic test. A case in point is that represented by bowel discharge antigen Type IB. A colored male with a positive Frei reaction developed a typical ulcerative colitis without stricture three years after the bubo involvement. Was the intestinal affection unrelated to his venereal disease? The answer rests on the fact that ten of eleven cases with positive Frei reactions were positive with his bowel discharge antigen; sixteen cases with negative Frei tests were negative to it.

(2) Bowel antigen may be important from a public health standpoint. Those indicating the presence of virus by a positive bowel antigen would seem to be public health menaces, in the sense that the extrusion of any material containing the virus may by contact disseminate this agent. The positive Frei reaction does not necessarily indicate the presence of virus in the bowel; the virus may never have been associated with the colitis or enteritis, or it may have disappeared from the intestinal involvement.

(3) The trend of experimental and clinical evidence points towards this virus as being a cause of the colitis with which it is associated (7). Because of the limitations of the Frei reaction, the bowel antigen is the only practical method at present which will demon-

strate the presence of this agent in the involvement.

(4) A positive bowel antigen secured especially from those in whom the clinical picture is not typical of the advanced stage of colonic involvement by this virus, the stage most widely known, would result in a different clinical approach to the problem.

A bowel antigen producing no reactions may indicate the absence of the virus or its presence in too small an amount in the material obtained for antigen purposes. If it is felt that the latter might be true, another attempt to secure more suitable material should be made.

A satisfactory positive bowel discharge antigen such as Type IB can be used in place of a Frei antigen. The bowel infection persisting for a much longer period results in a more constant source and obviates to some extent the difficulties surrounding the obtaining of adequate bubo pus from human beings.

SUMMARY AND CONCLUSIONS

1. Two positive bowel tissue and eight additional positive bowel discharge antigens, as well as seven control antigens from various sources are reported. Positive responses to bowel antigens indicate the presence of the virus of venereal lymphogranuloma in the material from which the antigen was made. Further proof in substantiation has been adduced by the production of positive Frei reactions in a male dog inoculated with unactivated bowel discharge from a patient from whom a positive bowel discharge antigen had been obtained. The trend of experimental and

clinical evidence points toward this virus as being a cause of the colitis with which it is associated.

2. A new method for the practical preparation and use of antigen of ante and post mortem bowel tissue is presented.

3. Bowel discharge and bowel tissue antigens render the diagnosis of lymphogranuloma venereum infection in the bowel more direct and specific and is important for the following reasons:

(a) The limitations of the Frei reaction as exemplified by anergy, and by the fact that the Frei reaction will not establish the presence of the virus in the bowel; also, the Frei reaction may be present as a result of a healed or unrelated infection.

(b) From a public health standpoint, since patients from whom a positive bowel antigen is secured would seem to be menaces. The positive Frei reaction does not necessarily indicate the presence of virus in the bowel.

(c) A positive bowel antigen secured especially from those in whom the clinical picture is not typical of the advanced state of bowel infection by the virus of lymphogranuloma venereum as it is generally known, would result in a different consideration of the problem.

4. A bowel antigen producing no reactions may indicate the absence of virus or its presence in too small an amount in the material obtained. When the latter is believed to be true, a repetitious attempt is desirable.

5. A satisfactory positive bowel discharge antigen such as Type IB can be used in place of a Frei antigen.

Note: Since this paper went to press, six additional bowel tissue and one vulval tissue antigens were prepared and studied. One was of fresh, unfixed ileitis tissue from a case failing to give any intradermal response to multiple active human Frei antigens. The others were of involved formalin-fixed tissue from cases having given positive Frei reactions: one of the vulva, one of the transverse colon, one of ileo-cecal region, two of the rectum and one of the sigmoid. One, the sigmoid tissue antigen, gave positive intradermal responses in six of ten cases positive to the Frei antigen, and gave no reactions in all of eight cases negative to the Frei antigen. The intradermal inoculations of the remaining antigens gave no reactions in any positive or negative to the Frei antigens. As noted, a positive intradermal response in those giving positive Frei reactions indicates virus presence in the tissue from which the antigen was prepared. The failure to react to such an antigen may not mean such absence.

DISCUSSION

DR. IRVING GRAY (Brooklyn, N. Y.): Dr. Paulson

is to be congratulated upon his intensive studies in evolving a technic for the practical preparation of a bowel antigen for intradermal use. The skin reaction after intradermal injection of this bowel antigen is analogous to the Frei reaction. Unfortunately little is known concerning skin reaction to virus antigen.

Further experimental work, especially in mice, would seem to be indicated in order to determine whether or not encephalitis can be produced by the use of the bowel antigen. Von Hamm and his co-workers have shown that approximately 15% of the colored population in New Orleans have positive Frei reactions in the absence of clinical Lymphogranuloma Venereum. Dr. Paulson has obtained a few false positive reactions. It would be interesting to know whether these false positive reactions persisted in the same individuals and also how many of the patients were negroes.

Dr. Coca recently informed me that Dr. Arthur W. Grace of the New York Hospital, working with mouse brain antigen, never had a false positive reaction. The mouse brain strain of Dr. Grace has been increasing in virulence so that now the emulsion is diluted 1-40 or 50 in testing rather than the usual 1-10. A papular reaction, excluding the zone of erythema is never less than 7 mm. The normal mouse brain reaction is seldom over 4 mm.; so that the interval between the control and the specific reaction has been widened. The work of Dr. Grace would indicate that false positive reactions do not occur.

I should like to ask Dr. Paulson if he did control skin tests with normal mouse brain?

Has Dr. Paulson ever seen a case of clinical Lymphogranuloma Venereum negative to the Frei test?

Is the use of bowel antigen more specific in the diagnosis than the Frei antigen?

Dr. Paulson has taken a conservative attitude. His intensive and careful studies would indicate that he is dealing with a virus. Whether it is the etiologic agent in the production of ulcerative colitis, in a small group of patients is as yet not conclusive.

Whether this virus is the activating factor or a secondary invader is still a question that must be answered. Definite proof of virus existence must, of course, depend upon its transmission to mice with the production of encephalitis. Once again I want to congratulate Dr. Paulson for his stimulating contribution.

DR. JOHN L. KANTOR (New York, N. Y.): I greatly admire this work and admit that I am no judge of many of the bacteriological details. I should like to ask Dr. Paulson a question. When he says this is a public health menace, what is his conception of the method of spread of the disease? Is it always venereal or has he some other aspect in mind? For those interested in terminology, it may be pointed out that this disease may be called, with equal propriety, either "lymphogranuloma venereum" or "lymphopathia veneria."

DR. ASHER WINKELSTEIN (New York, N. Y.): I think a better term for the disease is indeterminate ulcerative colitis. My impression of the etiology is that a few of the cases are unrecognized amebic colitis and perhaps 20 per cent are chronic bacillary dysentery, and in the rest, the etiology is unknown.

Dr. Paulson's purpose is to point out that a small per cent of those in this remaining indeterminate, 75 per cent are apparently the rectal and colonic types of lymphopathia venereum. Several years ago the idea occurred to me that perhaps some of the female ulcerative colitis patients started in primarily as the Frei disease of the rectum and spread upward. We therefore did Frei tests routinely in a large series of ulcerative colitis cases, first in females and later in males, because males not infrequently get rectal lesions of lymphopathia venereum. The tests were uniformly negative.

We then prepared filtrates of colitis tissue and colitis stools, and tested the skin of colitis patients and of con-

trols in quite a large series. We had over a couple of hundred control patients. In some colitis patients we got a typical skin lesion looking like a positive Frei test. However, we were not convinced by our findings that we had anything definite. It is distinctly possible that Dr. Paulson's work has a broader implication than that some of the cases of ulcerative colitis are lymphopathia venereum of the colon. The broader implication is that it is possible that some or nearly all cases of this 75 per cent "indeterminate" group, are due to another filtrable virus. I think efforts in the future should be devoted to an intensive study of that possibility.

DR. MOSES PAULSON (Baltimore, Md., closing the discussion): Some of the now obvious important implications of this work, just mentioned by Asher Winkelstein, were among the reasons why this study was undertaken. For a long while, I have felt the necessity of another approach in the etiologic studies of the indeterminate enteritides and colitides. My concept that viruses may be factors in some of the obscure digestive disorders resulted in the selection of the virus of lymphogranuloma venereum as

the starting point. It is a virus which gave indications of involving the intestinal tract. I believe that my researches have placed the study and diagnosis of intestinal lymphogranuloma venereum on a more direct and practical basis.

The work points out another approach to digestive diseases in the probability of other viruses living in the alimentary tract possessing possible pathogenic propensities, and has shown a group of cases heretofore designated and treated as indeterminate ulcerative colitis to be associated with—probably caused by the virus of lymphogranuloma venereum.

There is no published record of the purported work at Mount Sinai Hospital in New York City referred to by Asher Winkelstein.

The question of terminology raised by John Kantor has apparently been settled by the editorial staff of the Journal of the American Medical Association who insist upon "lymphogranuloma venereum." His query concerning public health aspects of this virus in relation to bowel antigen, has been discussed in the paper. This is also true of some of the problems brought out by the comprehensive discussion by Irving Gray.

Bacillary Dysentery: Late Results and Relationship to Chronic Ulcerative Colitis*†

PHILIP W. BROWN, M.D.

and

J. ARNOLD BARGEN, M.D.

ROCHESTER, MINNESOTA

ACCORDING to Hippocrates and Galen (2), dysentery was one of the great scourges of early times. They wrote of the "bloody flux," and down through the ages "diarrhea and dysentery" were of great concern. The medical literature of this country contains pages and pages of data on acute and chronic diarrhea and dysentery which occurred during the Civil War; it also contains the pertinent comment (10) that the "flux caused more sickness and mortality than any other form of disease." Likewise in the Spanish-American War (9) the incidence of dysentery among the American soldiers was 500 per 1,000 soldiers, but the mortality rate was lower, that is, 5 per 1,000, or 1/2 per cent among those who were infected. Hurst and Knott (6) described the ravages of dysentery among British soldiers in the Crimean and other colonial wars; their own experiences with dysentery in the World War led them to consider a probable relationship between chronic bacillary dysentery and what they had previously considered as chronic ulcerative colitis. They quoted Klemperer's similar observations among Austrian soldiers. Of course, the early records of dysentery are confused because of the unknown etiology of most types of the disease. Even the typhoid type was not recognized until the first part of the Nineteenth Century and the Eberthella typhosa was not identified until 1880. Recognition of Endamoeba histolytica in 1875, and the demonstration of Shigella dysenteriae and Shigella paradysenteriae in cases of dysentery in 1898 and 1900, respectively, made it possible to establish some of the different types. The medical records of both the

British and American armies indicate the occurrence of tremendous dysentery epidemics. According to the Medical Department of the U. S. Army (9), the incidence of dysentery in the World War was 0.05 per 1,000 soldiers as compared with an incidence of 494 to 850 per 1,000 soldiers in the Civil War (10). There were 4,546 recorded cases of dysentery or diarrhea of all types among 4,000,000 American troops in the World War and only eighty-five men were discharged because of disability resulting from dysentery (9). This is by no means a true incidence of acute diarrhea, as various medical officers noted that fully 70 per cent of the command suffered from diarrhea but only a few were hospitalized.

The British literature contains many data on this disease and the writings of British authors and the reports of many other writers make frequent mention of chronic dysentery which follows on the heels of an acute infection. We have been unsuccessful in finding any figures which give the incidence of the chronic dysentery which developed from the acute dysentery. Hurst and Knott mentioned the fact that in chronic dysentery, the dysentery bacillus may persist in the stools for months, but that it gradually becomes increasingly difficult to culture it from the feces. The proctoscopic and roentgenologic features of chronic dysentery resemble those of chronic thrombo-ulcerative colitis. Hurst and Knott have long felt that chronic ulcerative colitis is not a disease entity but a later stage of bacillary dysentery. This impression has been affirmed and denied by investigators in many countries. Felsen utilized an opportunity to study an epidemic of bacillary dysentery in 1934. He made a

*Read before the meeting of the American Gastro-Enterologic Association, Atlantic City, New Jersey, May 2-3, 1935.
†Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

follow-up study in 122 cases and found that regional enteritis or chronic ulcerative colitis developed later in 10 per cent.

Kinsella reported that, during the summer of 1921, in various towns of Minnesota, Oklahoma, Indiana and probably in Iowa and South Dakota, there occurred a widespread epidemic of dysentery which was proved to be the result of the Flexner strain of *Shigella paradysenteriae*. Many cases were observed in Rochester, Minnesota, and a group of 140 cases was reported by him, although this group represented only a part of the cases of dysentery that occurred at that time; furthermore, the peak load of summer work limited the opportunities for repeated bacteriologic examination of the stools. He said that in the 140 cases the *Shigella paradysenteriae* (Flexner) was identified in forty-five instances. One cannot conclude that, because a third of a group of patients were suffering from dysentery and were found to be harboring the Flexner strain of *Shigella paradysenteriae*, the remaining two-thirds harbored this same organism. However, Kinsella found no other pathogenic organism in the stools during that period. Because of the technical difficulty of obtaining cultures and the clinical and laboratory load at that time, it is not unreasonable to assume that the cause of diarrhea in all of the cases was the Flexner strain of *Shigella paradysenteriae*.

To judge from various comments, the morbidity of the infection must have been high; "everybody had diarrhea that summer!" There were fifteen deaths in the 140 cases, and fourteen patients came to necropsy. Kinsella obtained positive cultures of *Shigella paradysenteriae* in six cases in which death occurred. In five of the nine cases in which positive cultures were not obtained there was ulceration of the bowel that was characteristic of bacillary dysentery, but in the remaining four cases there was no ulceration. In each instance an attack of acute diarrhea preceded the death of the patient. In three of the six cases in which the cultures were positive the dysentery was a post-operative complication and contributed to the fatal outcome. One child, two and a half years of age, died as a result of dysentery and necropsy revealed a pseudomembranous ileocolitis. In two other cases the post-operative attack of dysentery may have borne some relationship to death. Hence ten of the deaths were in cases in which the dysentery occurred after an operation. In four of the cases in which operation was not performed, the dysentery complicated practically hopeless conditions and was "the last straw." It is obvious that fifteen deaths in 140 cases is not the slightest indication of mortality as there were many more than 140 persons who were suffering from dysentery at that time. It, however, does show that the strain of *Shigella paradysenteriae* was very virulent, and that, in cases in which the patients were infants or elderly persons, or had any serious disease or had become debilitated as a result of a malignant growth, the dysentery precipitated the fatal outcome. It is only repetition to show pathologic specimens, but the appearances of the intestine in some of the cases certainly impress one with the severity of the infection.

A study of the late results of the cases studied by Kinsella has just been completed. It is more than sixteen years since the epidemic; therefore the data are not as complete as one would wish. Fifteen patients died during the epidemic. Twenty-three

patients could not be traced but they apparently were well when they were dismissed. Twenty-four patients died months or years after their dismissal. These patients also apparently were well and had no intestinal symptoms traceable to this epidemic. Seventy-seven patients are known to have lived for one to seventeen years and did not have any intestinal symptoms after their dismissal.

In one case, intestinal symptoms were present until 1929, when they disappeared. Sigmoidoscopic examination in the fall of 1921 revealed what we classified as "early chronic ulcerative colitis" but a roentgenogram of the colon disclosed that the process did not extend beyond the rectosigmoid. For eight years this patient continued to have moderate symptoms and various forms of therapy were administered. In 1925 the diplostreptococcus of thrombo-ulcerative colitis was isolated and a vaccine was prepared. In the eight years the disease persisted, repeated roentgenograms of the colon did not demonstrate extension of the disease beyond the rectum. Oddly enough, after a hysterectomy was performed in 1929 the intestinal symptoms disappeared and in 1938 the patient had not noted any return of the disease. Is this a spontaneous recovery or is it merely a prolonged remission?

Among one of the group in 1921 there was one patient who had ulcerative colitis and who had been under treatment at the clinic for four years prior to the epidemic. During the epidemic she had had an exacerbation of the colitis but this had subsided without causing any serious consequences. This patient died ten years later of pulmonary tuberculosis; no doubt her resistance had been depleted by ulcerative colitis (not tuberculous) which had been present for many years.

We realize that this review, which was made sixteen years after the epidemic, is not comparable to Felsen's careful follow-up study of the 122 cases observed during the Jersey City epidemic. The value of careful intestinal studies in our cases in 1921 was by no means as apparent then as it is now. Likewise, this final paragraph on the Rochester epidemic is merely what we could learn from this particular "sample" and certainly does not permit any generalizations.

We do feel that bacillary dysentery is a widespread disease. With continued improvements in sanitation, the terrific epidemics of the past centuries and even those of more recent years are becoming less and less. If chronic ulcerative disease of the intestine develops only in one of every 100 cases of acute dysentery, the suffering in that one case warrants every possible effort to stamp out dysentery!

From another angle, it is somewhat puzzling to harmonize the world-wide extent of bacillary dysentery with the suggestion that dysentery may be a forerunner of chronic regional enteritis and thrombo-ulcerative colitis. The latter diseases fortunately are not common conditions. Kopelowitz compiled the following figures on the number of cases of ulcerative colitis observed in various hospitals: at the Peter Bent Brigham Hospital, seventy-four cases in twenty years; at the Massachusetts General Hospital, 149 cases in twenty years; at the Mt. Sinai Hospital (including *B. dysenteriae* and amebiasis) 125 cases per year, and at the Cedars of Lebanon Hospital (Los Angeles), thirty-four cases in seven years. A further idea on the relative infrequency of chronic ulcerative colitis is seen in a report by Hurst (5) who noted 288 cases of chronic

ulcerative colitis which have been recorded by seven London hospitals up to 1909; and from 1917 to 1926 (during and after the World War) fifty cases in Guy's Hospital; while in the Birmingham General Hospital he quotes Hardy and Bulmer on ninety-five cases from 1920-1932. Probably the largest series of cases of chronic ulcerative colitis is that of The Mayo Clinic, which consists of approximately 2,500 cases which were observed in thirty years.

For years we have been concerned as to the possible relationship of acute bacillary dysentery to a later condition that we have considered as an entity, namely, "chronic thrombo-ulcerative colitis." Following Hurst's (4) report in 1921, several of our patients who had ulcerative colitis were treated with antidyentery serum under the supervision of Dr. A. H. Logan. The results were discouraging. In 1931, Bagen, Buie and Copeland carried out cultural and agglutination studies for the dysentery group of organisms in fifty-seven consecutive cases of chronic ulcerative colitis but were unable to establish any relationship.

In view of renewed discussion of this problem, and because we felt that a difference in laboratory technic perhaps might have been responsible for our failure to find organisms of the *Shigella* group in these cases, when some of the workers in New York were reporting the presence of these organisms in some cases, Dr. Luther Thompson of the Department of Bacteriology of The Mayo Clinic interviewed Dr. T. T. Mackie in his New York laboratory. He obtained from him his exact technic of making cultures. We were supplied with five strains of dysentery organisms, which in turn had been obtained by Dr. Mackie from Professor E. G. D. Murray of McGill University. Our analysis revealed that three of these strains belonged to the Flexner strain of *Shigella paradysenteriae*, one was a strain of *Shigella dysenteriae*, and another was a Sonne-Duval strain of *Shigella paradysenteriae*. These organisms were used in our agglutination studies. Material for culture was obtained through the sigmoidoscope, and cultures were made immediately following accepted methods, including those of Dr. Mackie. During 1937, thirty-five consecutive cases of chronic ulcerative colitis were studied in this manner. The patients lived in the following places: Ten in Wisconsin, six in New York, three in Nebraska, two each in Michigan, Iowa, Ohio and Kentucky, and one each in New Hampshire, Indiana, Illinois, Montana, South Dakota, North Dakota, Saskatchewan and Alberta. They came to the clinic directly from their homes. In only one instance was an organism of the *Shigella* variety isolated from the ulcers in the rectum and sigmoid colon; this proved to be a *Shigella paradysenteriae* (Flexner). Likewise, there was a high agglutination titre of the serum. No opportunity for study of this case was granted as the patient found it necessary to return home for treatment. It is of some interest that in this case the symptoms of colitis had occurred slowly over a period of seven months.

During the time of this study other cases which we recognized as cases of other varieties of dysentery came under our observation, and the stools or material obtained through the proctoscope, which was cultured in the same way, yielded four strains of organisms of the *Shigella* variety. In these cases the cultures were made in the same manner as the cultures in the cases of chronic ulcerative colitis. In one of these the culture

revealed *Shigella paradysenteriae* (var. sonnei). This culture was obtained in a case of a very severe, destructive ulcerative colonic disease, which was not chronic thrombo-ulcerative colitis. Curiously enough, the patient's serum did not agglutinate the Flexner or Sonne strain of *Shigella paradysenteriae*. Strains of *Shigella dysenteriae* were isolated from three other cases of diarrhea in which there was no ulcerative process in the intestine.

In a few cases of regional enteritis, agglutinating properties of the blood have been tested against these strains of *Shigella*. In two instances cultures of the stool for the *Shigella* were negative but an agglutination titre of the serum in a dilution of 1:320 in one case and 1:160 in the other case, for the Flexner strain of *Shigella paradysenteriae* was noted. A vaccine made from the Flexner strain of *Shigella paradysenteriae* was administered, but the benefit was doubtful. In two cases both cultures and agglutination tests were negative. These few cases are of no significance and do little more than confuse the issue, as we have too few data to hazard any opinion as to etiology of regional enteritis.

SUMMARY

The results in 140 cases of epidemic dysentery were studied. In forty-five of these cases cultures of the stools yielded the *Shigella paradysenteriae* and the cases were reviewed sixteen years after the occurrence of the epidemic. A form of chronic ulcerative colitis developed in only one of the cases. The incidence of intestinal ulceration of a chronic type following large epidemics of dysentery during wars is exceedingly small. Intensive cultural and serologic investigations of the lesions of typical chronic thrombo-ulcerative colitis for organisms of the *Shigella* variety have yielded largely negative results. The results of serologic studies in cases of regional enteritis have been inconclusive in so far as we have data.

As a result of these observations we do not feel that there is sufficient evidence to consider the *Shigella* group of organisms as the cause of chronic thrombo-ulcerative colitis.

DISCUSSION

DR. T. T. MACKIE (New York, N. Y.): Mr. President and Members and Guests: Dr. Brown has sounded a very much needed note of caution, concerning the potential importance of bacillary dysentery in the subsequent development of some of the chronic diseases of the intestinal tract. There is conflict of opinion concerning the relationship of the *Shigella dysenteriae* to these chronic conditions. It is said by a number of the British workers that about 5

per cent of all cases of bacillary dysentery become chronic and present the morphological and clinical picture of so-called idiopathic ulcerative colitis.

It is also said that the majority of these cases of chronic dysentery result from infection by the Shiga bacillus, and that the Flexner strains are relatively unimportant types, yet this statement is not universally accepted. L. S. Dudgeon, reporting from England, a group of chronic cases developing during the war, found that some 54 per cent followed upon continued infection by the Flexner bacilli.

In this country increasing attention has been focused upon these organisms in the last few years. Some workers maintain that they play a highly important role in the development of chronic intestinal disease. Frequently these diagnoses are based upon the agglutination reaction rather than culture. This method of diagnosis is not above criticism.

We have studied the curves of dysentery agglutinins in a group of patients over a considerable period. The following observations in two cases are characteristic of the group.

Case 1 was studied for forty-two months. This patient had a total of twelve positive cultures for the bacilli from twenty-two attempts which were more or less evenly spaced throughout.

The homologous agglutinin titre at no time rose above a dilution of 1/320, the initial level. Later the homologous agglutinin titre fell to zero, subsequently rising in a brief period again to 1/320. This patient showed a sustained titre of 1/160 for the Sonne bacilli.

The second patient was under observation for twenty-six months. Twenty-nine negative cultures were obtained from the rectal mucosa. The same variability of the agglutinin titre curves was observed. Agglutinins for the Sonne Bacillus reached a dilution of 1/640 on five different determinations, and the curve showed considerable fluctuation. The Flexner titre started at 1/320, dropped to zero, rose to 1/320, fell to 1/160 and again to zero, finally rising to 1/160 up to 1/640. Shiga agglutinins were not present.

Both of these were cases of so-called idiopathic ulcerative colitis.

It has been our experience, therefore, that the agglutination reaction is not a dependable diagnostic procedure. Furthermore, we have been able to demonstrate in the experimental animal the production of dysentery agglutinins by heterologous immunization using strains of *Escherichia coli*.

I wish in closing, to emphasize the necessity for caution in the interpretation of the agglutination reaction in the absence of confirmatory cultures.

DR. BURRILL B. CROHN (New York, N. Y.): It is an old dispute, this question of dysentery. It should be pretty well understood there is a great deal of dysentery throughout the country, as Dr. Brown has said. It should be emphasized that the reports of the Public Health Service of this country show dysentery current through all the states of the country practically all the time, and such centers as Pennsylvania and Massachusetts show dysentery in their states every month of the year and in successive years.

To quote an instance, a case of severe ulcerative colitis seen in Brooklyn, with 104° temperature, diarrhea for several weeks; there was supposedly no contact with any other patient suffering from diarrhea. Nevertheless dysentery was suspected. We found it in the colored maid discharged because of illness, diarrhea; she proved to be a dysentery carrier, and a food carrier in that particular home.

One thinks of dysentery in people returning from the

tropics. I examined a husband and wife just returned from Mexico a few months ago. The husband had diarrhea for two months and had had the typical sigmoidoscopic picture, a definite, subacute proctitis with positive cultures for dysentery bacilli; he was given dysentery serum and antiseptic irrigations before the rectum cleared up.

The British workers found there is a definite form of chronic dysentery. You know that the cities on the Eastern seacoast are repositories for people returning from the tropics, and we have a tremendous population cruising in the West Indies and the tropics; the return of these people by the boatload with diarrhea is a common occurrence. The diarrhea breaks out usually when the boat is three days away from the Coast. (The incubation period of dysentery is about three days). Repeatedly the story is told, "We were well until we were three days out and then everybody in the first cabin was taken with dysentery." It is not generally known that the distribution is not by drinking water or milk, but the British Commission in their work in Syria pretty well proved that the distribution was by flies.

For some time I have thought certain parts of New York City more infected with ulcerative colitis more so than other parts; I thought a survey of the City of New York would prove that there were distributing centers for ulcerative colitis. Contact cases might be suspected, as in my experience I was able to publish two cases of ulcerative colitis in sisters. This is a rare disease and to occur twice in one family was suspicious of a contaminating organism. I reported also regional ileitis in a sister and brother—that is unusual. Both were successfully resected. Such occurrences raise the suspicions of a common bacterial origin for the diseases.

With the assistance of the Board of Health, I was able to plot out the cases of ulcerative colitis in New York. I was disappointed in the chart. I thought I would be able definitely to show there is an area in Brooklyn and there was a small area in East New York where there was a common infecting agent giving rise to chronic ulcerative colitis. Some places in the Bronx impressed me with the idea that there must be some contaminating factor. But when I plotted out the several hundred cases of ulcerative colitis in 1936 in Greater New York, it was obvious that the disease followed the trend of the population and the concentration of the population in the city. There were no specific areas in the city which I could constitute distributing centers.

(Slide used to show result).

DR. PHILIP W. BROWN (Rochester, Minn., closing the discussion): I am grateful to Dr. Mackie and Dr. Crohn for their comments.

The problem, again, has been to me, as I have attended these meetings and worked with these patients over a period of some few years, is that of not defending any particular "belief." I have been impressed by the fact that there is something in the soil of these people that permits this process to go on.

Dr. Crohn has mentioned that he has had an occasional pair that have occurred in one family. In our group of figures that Dr. Borgen presented at the College of Physicians recently, of some 2500 cases of ulcerative colitis, I think there are about twenty or twenty-five pairs, a father and son, a brother and sister, two members of the family that have the disease, but out of that rather large group it is remarkable there are so few that occur in the same family, and it is just the constant reiteration of endeavoring to keep our minds open on this problem and not allowing ourselves to be paralyzed by a "belief"—a "belief" is apparently a rather difficult thing to get around.

Studies of Adenomatous Polypi and Carcinoma of the Colon*

By

PAUL KLEMPERER, M.D.

NEW YORK, NEW YORK

THE problem of the carcinomatous transformation of adenomatous polypi of the colon is of practical and theoretical interest. The occurrence of such a transformation is generally accepted. However, the question as to the frequency of such a development has not been answered unanimously. It would hardly be possible to give due consideration to even a fraction of the literature on the subject. For this reason mention will be made only of the recent investigations of the surgical clinic of Professor Schmieden in Frankfurt and of the pathologic institute of the late Professor Maresch in Vienna because these investigations have dealt exhaustively with the whole complex of problems and have, nevertheless, come to rather opposing conclusions. It seemed, therefore, not amiss to investigate again the question, particularly because there was ample material available for study. Two questions seemed of particular interest: 1. How frequent is the carcinomatous transformation of adenomatous polypi? and, 2. Are there any histologic criteria to recognize those polypi which are likely to become carcinomatous? The same questions have been discussed by the authors previously mentioned. The reason for their divergent conclusions may be attributed in part to the fact that Schmieden and his group studied only surgical material while Maresch and Feyrter investigated only autopsy material.

I had at my disposal a large number of resected specimens, many polypi which had been either biopsied or resected, and sufficient autopsy material. However, for statistical data regarding the frequency of the association of carcinoma and polypi of the colon, 103 resected specimens of the last year only were utilized. This seemed advisable because only within the last year has the necessary careful attention been applied in the examination of the specimens, without which small polypi are so easily overlooked. For the same reason the necropsies of the last 6 months only were used to establish the frequency of polypi in routine autopsy material. Every actual mucosal proliferation was counted even if only a few mm. in diameter. The major part of these polypi was examined histologically. Finally, all the sections of polypi which were submitted for diagnosis within the past ten years, have been re-examined and classified. This material was of greatest value because a considerable number of cases had been followed up for a period of several years. Thus, the histological picture could be correlated with the clinical course.

Investigators who believed in the great frequency of carcinomatous transformation of colonic polypi have based their belief not so much upon a great number of actual observations, but rather upon a seemingly most conspicuous association of colonic carcinoma with polypi. Such association among surgical material seemed the more significant because the only statistic available dealing with the frequency of polypi in

routine autopsy material reported a low percentage of 0.7 per cent only. However, these often quoted figures of Staemmler are evidently incorrect as shown by the recent figures of Feyrter. He found among 1,800 successive autopsies, polypi in 386 cases and a total number of 1,017 polypi because there were several polypi in many cases. The percentage was 21.5 for the total number. If, however, the figures were computed for the decades, the percentage rose in the older age groups to reach 77 per cent at the age of 75 and over.

My total percentage is the same as in Feyrter's observations, but the percentage in the older decades is lower. The percentage of polypi in autopsy material is higher than that found in 103 surgical resections (17.5 per cent). These figures and those quoted by Feyrter approach or even surpass the surprisingly high percentage of 45 per cent polypi found by Schmieden and Westhues in a small series of resected carcinomas. The fact that in unselected autopsy material, polypi are so frequent, especially in the higher age groups, makes it obvious that a frequent association of polypi and carcinoma can not serve as the basis for a computation of the frequency of carcinomatous transformation of polypi. Another source of erroneous frequency figures is the confusion of the situation in diffuse polyposis of the colon with that existing in single or multiple polypi of the colon. The excessive frequency of carcinomatous transformation of the polypi in diffuse polyposis is well established. But there is no reason to identify and confuse this rare, evidently hereditary condition with the most common isolated polypi of the colon.

Actual frequency figures for the carcinomatous transformation of polypi can be calculated if one establishes the actual number of polypi which show carcinomatous transformation and the number of carcinomata which still show the microscopic features of a pre-existing adenomatous polyp. Table I and II shows the figures for the material at my disposal. It is important to note that the routine necropsy material showed a much lower incidence.

Before entering upon the question of the histologic differentiation between harmless and suspicious adenomatous polypi, the distribution of polypi may be shortly evaluated because a supposed predilection of the rectum and sigmoid was accepted as an evidence of a causal relationship between polypi and carcinomata inasmuch as the latter certainly favor the rectum and sigmoid.

A striking predilection for rectum and sigmoid is not evident for polypi as for carcinomata. More than 75 per cent of the latter are found in these parts of the colon, while only 43 per cent of polypi are found in rectum and sigmoid.

The question of histologic criteria for the differentiation between innocent and potentially malignant polypi has occupied the interest of pathologists for many years. Hauser was the first to demonstrate that

*From the Laboratories of The Mount Sinai Hospital, New York City.
566

a large number of polypi consisted of glands not identical with the crypts of Lieberkuehn. They were branching and lined by high columnar epithelial cells, not by goblet cells. He regarded these cells as dedifferentiated cells and polypi of this type as potentially

TABLE I

Distribution of polypi in necropsy material

Cecum and Ascending Colon	23
Transverse and Descending Colon	36
Sigmoid and Rectum	44

malignant. Versé in his classical monograph, has taken a similar point of view and has indicated that further cell atypism may be accepted as an evidence of an irreversible cytological change necessarily leading to carcinoma. Schmieden and Westhues have classified colonic polypi according to these cytologic differences and also according to their architecture into three groups. The first type is practically always harmless, while group II and especially III are potentially malignant. This classification is too narrow from a purely descriptive point of view and a good number of polypi can not be properly classified. This holds true for the villous adenomata which form a special group. There are such great variations in the size and shape of the glands, and the type and arrangement of the cell lining that it is hardly possible to give a satisfactory classification.

No single criterion exists which could be accepted as a reliable index for the malignant potentiality of a given polyp. Multilayering of dark rod-shaped nuclei in cylindrical cells or numerous mitotic figures, while always found in polypi which show carcinoma development, can also be detected in polypi incidentally found at autopsy or in instances in which the clinical course indicates the innocence of the lesion. However, the villous adenomas show such a high percentage of malignant transformation that this type should always be looked upon with some suspicion. In general, the frequency with which polypi have been found to be carcinomatous in the clinical polypi studied, warrants their destruction whenever encountered. However, inasmuch as a differentiation between those which are precancerous in a strict sense and those which are innocent can not be made microscopically, conservative treatment must be sufficient. In connection with this

TABLE II

Frequency of carcinomatous transformation of polypi in clinical and autopsy material

Source	Number	Carcinoma	Percentage Carcinoma
Polypi found in colons resected for carcinoma	79	18	22.7
Polypi either biopsied or excised	99	14	14
Polypi found in autopsy material	66	4	6.0

There were actually 122 polypi available for examination. However, 23 found in patients below 20 years were deducted from the total.

recommendation mention must be made of three pedunculated polypi with fully established carcinoma, but without invasion of the pedicle in which resection of the polypi only was done. These patients have been followed for 4 years and are symptom free.

DISCUSSION

DR. BURRILL B. CROHN (New York, N. Y.): I consider this paper a valuable contribution. If, during a routine sigmoidoscopy, one encounters polypi, my suspicions regarding carcinoma are always aroused. I am a little disabused of that idea by hearing Dr. Klemperer's paper because I realize the wide distribution of polypi throughout the colon, and the common frequency with which they occur.

I note from the tables shown that the increase of polypi is greater with the successive decades; there are many more polypi in the colon in the fifth than in the fourth, and in the sixth than in the fifth, and so forth. I had an idea they were probably all congenital, and that they were all there at birth. Perhaps, there is an inflammatory factor, or a factor of degeneration in the intestinal mucosa; perhaps the increase of polyps in successive decades would possibly account for the greater incidence of carcinoma in the later years.

A word of warning about biopsies during sigmoidoscopies, and this too I learned with Dr. Klemperer: In one case there were two negative biopsies taken from the polyp, yet I had every reason to be suspicious. The third biopsy showed a carcinoma; the resection of the growth showed an advanced malignant degeneration of a polyp. In spite of surgical operation the man died within a few months of widespread metastases.

I should like to warn against negative biopsies in a case clinically suspicious of carcinoma. I have assumed the attitude that negative biopsy or not, if I have a sufficient clinical suspicion, and the appearance through the sigmoidoscope is sufficiently suggestive of carcinoma, I am willing to disregard the negative biopsies and ask a surgeon to resect.

May I ask Dr. Klemperer a question about the incidence of multiple carcinoma in the colon where two or three carcinomas not infrequently take place in one colon, whether there is a relationship between multiple carcinoma and the incidence of polypi? He did not mention the incidence of congenital polyposis. I should like to hear his viewpoint in that regard.

DR. JOHN L. KANTOR (New York, N. Y.): I think we are all very grateful to Dr. Klemperer for such a beautiful presentation. If it is true that you have to section a whole polyp to find one little area of malignancy in it, then it must follow that there is no great use in taking a biopsy specimen since it may obviously miss the malignant area. Therefore, it seems to me that the only thing one can do is to train his eye, his clinical sense, and his clinical judgment, so that he can decide when certain appearances in the proctoscopic picture are sufficiently

suspicious to warrant removal of the polyp. I think it is unfair to lean upon the pathologist. In other words, a thing either looks suspicious or it doesn't, and it is the clinician's responsibility to make the decision.

DR. PAUL KLEMPERER (New York, N. Y., closing the discussion): If I may take up the question as to congenital diffuse polyposis, that is a different problem. These cases, which number, according to the literature, about two hundred, and probably many more which have not been published, show an exceedingly high percentage of carcinomatous transformation. This type of diffuse polyposis should not be confused with the condition of single or few polypi as they are found so frequently at autopsy and also clinically. These cases are commonly familial.

Considerations as regards the frequency of carcinomatous transformation of adenomatous polypi have often been based upon this condition, which is evidently incorrect.

In regard to the biopsy and the necessity of biopsy, I somewhat differ from Dr. Kantor. It is true that the pathologist can not be called to account if he gives a negative diagnosis in a case which later turns out to be carcinoma; nevertheless, in the greater majority of these carcinomatous polypi, as I have shown you here, the diagnosis at biopsy was positive. I wanted only to demonstrate with these specimens that even in a case in which there is a definitely established carcinoma on a polyp, the adeno-

matous areas, which are not yet carcinomatous, do not give any evidence as to the probability that they may become carcinomatous.

I think one should make an attempt to establish the diagnosis by biopsy. The question about which, however, I still puzzle is what to do about the carcinomatous polypi, not the huge ones, which, of course, have to be resected radically, but the smaller pedunculated ones, the size of a cherry and even slightly larger. Is it necessary to resect?

Dr. Crohn quoted one of these cases. I am not quite sure that, when we saw the specimen, it still showed the polypoid appearance. I remember, however, another case where there was no question of the polypoid origin of the carcinoma, the patient dying with metastases after having symptoms for five years or more, but in this case the pedicle was already infiltrated.

I would express the opinion today, though still with reservations, that adenomatous polypi with early carcinoma need not be resected radically, but excision with surrounding mucosa is sufficient.

I hope in a few years to have more material and give more reliable information. Today my material consists only of four cases. These four cases were watched over a period of three and four years, and the patients are perfectly well.

Another point is that polypi that are histologically not carcinoma, and are, therefore, only potential carcinomata can be successfully treated with simple coagulation.

A Study of Gall Bladder Function*

By

H. NECHELES, M.D., Ph.D.
CHICAGO, ILLINOIS

RESULTS obtained with the Graham-Cole gall bladder concentration test do not depend on the function of the gall bladder only, but on a number of other factors.

1. Absorption of dye from the intestine
2. Excretion of dye by the liver
3. Concentration of dye by the gall bladder
4. The effectiveness of the motor meal
 - a. Retention in the stomach
 - b. Absorption in the intestine
 - c. Contraction of the gall bladder and relaxation of the sphincter of Oddi and the duodenum.

Except under rare conditions the time given for intestinal absorption and for hepatic excretion of the dye is sufficient for yielding positive results even when both of these functions should be somewhat impaired. The concentration of the dye by the gall bladder is the function to be tested. To the roentgenologist and physiologist the effectiveness of the motor meal seems to be one of the most difficult technical parts of the gall bladder concentration test. Normally fats delay the emptying of the stomach for many hours. If a fat meal produces nausea, and it does in a number of

cases, then pylorospasm and reversed peristalsis will prolong this delay. The roentgenologists are aware of this and X-ray pictures of the gall bladder are taken for periods of one to three or more hours after the motor meal. When rapid motility of the upper part of the small intestine is present the fat meal is transported into the ileum and its motor effect on the gall bladder is diminished if not abolished. Some patients are allergic against milk, egg, etc.

The mechanism by which fat produces contraction of the gall bladder and relaxation of the sphincter of Oddi is not known. So far Ivy's cholecystokinin seems to offer the most logical clue but unfortunately our preparation have not proven very effective, nor has Ivy as yet produced a pure substance of constant biologic properties. The following work was done therefore in order firstly, to elaborate a simple test on gall bladder function in normal animals, and secondly to find a drug which would make a normal gall bladder empty itself.

Experimental work on the gall bladder has been hampered by lack of simple methods. In man, castor oil, fasting, taking of dye, enemas, a fat meal and the time factor make it nearly impossible to perform a large number of tests on the same individual not to speak of the cost of films and of the uncertainty of obtaining all important phases on the films. In experimental animals on the other hand, technical difficulties

*Aided by the Oscar Aberle Fund.

Reported at the meeting of the American Gastro-Enterological Society, Atlantic City, 1935.

From the Department of Gastro-Intestinal Research, Michael Reese Hospital.

and cost of films have proven to be preventive to us to test the effect of a large series of drugs on the gall bladder. Acute experiments in which the gall bladder is filled with radio-translucent substances and in which tests are done after the animal awakens from the anesthetic have the disadvantage of abnormal conditions and can hardly be repeated on the same animal. We have therefore developed a simple gall bladder function test in the normal dog similar to the one used by Winkelstein (1) and by Gianturco and Kirklin (2). In an aseptic operation four small lead beads are sewn on the serosa of the gall bladder; 2 on the longitudinal and 2 on the horizontal diameter. Experience in handling of the tissues and the use of papain and citrate solution prevents or minimizes adhesions. The four beads are seen easily with the fluoroscope and are marked on transparent paper. Their distance is measured before and after administration of drugs. The dog is always kept in the same position during each fluoroscopic examination. Control observations without drugs have

variation of 12 hours. No dye is used; no X-ray pictures are taken; no castor oil or enema need be given because the beads are clearly visualized. A number of drugs can be tried in a short time. The new method is simple, rapid and cheap for experimental purposes.

TABLE 1.

The first group of drugs tested belong to the adrenal group. They were chosen because some of them have been described to contract the gall bladder and because some of them were expected to relax the small intestine simultaneously. This was important from the point of view that simultaneous contraction of the gall bladder and of the sphincter of Oddi or duodenum would not permit emptying of the gall bladder. As you can see from the data only adrenalin had a motor effect in that it effectively emptied the gall bladder in most tests. We were not surprised to find that benzedrine sulphate produced a dilatation of the gall bladder because in previous studies we convinced ourselves that administration of this substance evoked

TABLE I
Pharmacology of dog's gall bladder

Drug	Contraction	Dilatation	Indeterminate or no Effect	Drug	Contraction	Dilatation	Indeterminate or no Effect
Adrenalin	7	1	1	Methylguanidin	1	3	6
Ephedrin		2	1	Ergotrate			2
Neo Synephrin	1		3	Ergonovine		3	1
Benzedrine		2	1	Morphine	1	3	2
Benzedrine + Trasentin		1	2	Morphine-Atropine	2		1
				Papaverine	1	1	2
Pitressin	2	1	2	Olive Oil	21		1
Acetylcholine	2X	3	1	Olive Oil Extract	3	1	
Acetylcholine + Adrenaline	1	1		Egg Yolk	4		
Mecholyl	2		3	Milk-Cream	8

Yohimbin	2	2		Syntropan		2	
Histamine	2		3				

shown that only small rhythmic variations in the size of the gall bladder occur, not exceeding ± 3 mm. A meal of olive oil has been used to test the contractability of the gall bladder. Since in such a meal both diameters contract considerably only such results were termed contractions in which both diameters shortened, and likewise relaxation was assumed to have occurred only if both diameters had lengthened. This was based on the observation that following injection of atropine or diphenyl-acetyl-diethylamino-ethanol-HCL (trasentin),† both of them powerful dilators of the gall bladder, a lengthening of both diameters was observed in practically every case. Only such experiments are reported in which the dogs were in perfect health. The method reported has the advantage that the dogs need no preparation except star-

pylorospasm as well as duodenospasm in man and dog (3). We therefore combined this substance with Trasentin because we expected to obtain relaxation of the duodenum by the latter drug and contraction of the gall bladder by the former. The results did not bear out this assumption. The next group of substances are such that act either on smooth musculature directly or through the vagus nerves. As you see from the table, none of them acted with such regularity as adrenalin. The choline esters produce contraction of the gall bladder and a strong contraction of the duodenum of which we convinced ourselves in acute and chronic experiments. We tried to overcome this with combinations of acetylcholine and adrenalin but without success. In view of recent publications we had expected more clear-cut results from morphine. It makes a great deal of difference, apparently, whether one tests the gall bladder only or the physiological entity

†Generously supplied by the Ciba Company.

of gall bladder, sphincter of Oddi and duodenum. The next group represents the functional controls of our experiments on emptying of the gall bladder, namely the use of substances of which we could expect contraction and dilatation in practically every case. You see the great effectiveness of olive oil, egg yolk and milk and cream. Some simple extracts of olive oil with saline injected intravenously were effective also in contracting the gall bladder but this work is still in the experimental stage. Of the well known antispasmodic drugs of the gall bladder, sodium nitrite and atropine sulphate have been used. A new drug, Trasentin, has been tried also and has been found most effective. This drug had been previously tried in acute experiments in which we convinced ourselves that it had little effect on salivation, on the cardiovascular system and on the pupil; it was found to relax the gall bladder, contracted by barium chloride, pilocarpine, acetylcholine, vagus stimulation, etc. Its relaxing effect on the normal gall bladder of dogs (with beads on the gall bladder) was comparable to that of atropine.

In summary it may be said that with the method described above drugs can be tried easily on normal dogs without dye and without the use of X-ray films. The motor fat meal has been criticized and a number of contracting drugs have been tried among which adrenalin given intramuscularly seems to be the most promising. Among relaxing substances a new synthetic drug, Trasentin, has been found most effective.

DISCUSSION

DR. HENRY J. TUMEN (Philadelphia, Pa.): Mr. Chairman, Ladies and Gentlemen: Dr. Necheles has shown a great deal of ingenuity in applying to the gall bladder and the study of its function, this particular method. It is similar in some respects to a method used by Barcroft in the study of splenic contraction and, I believe, by MacSwiney in a study of gastric motility.

The particular virtues of this method are those he already has emphasized, its ease of applicability in the experimental animal, and the fact that it can be repeated without too much expense, and sufficiently frequently to warrant confidence in the results it gives. There is certainly a great deal of need for a method like this because of the confusion that exists about certain phases of gall bladder physiology and pharmacology. One has only to review the literature to see the great deal of confusion that does exist about the use of certain drugs and their action upon the gall bladder, and about certain other problems to which a method like this can be applied, such as the emptying of the gall bladder during pregnancy in animals.

Dr. Necheles has already mentioned the fact that he believes the gall bladder and the sphincter of Oddi and the duodenum must be considered together. The results obtained depend upon the functioning of all three parts of this unit.

It is to be hoped that some of the experiments with drugs will be repeated in such a way that isolated gall bladder action can be determined. Some of the results that Dr. Necheles has mentioned are not in agreement with current conceptions. If we take adrenalin as an example, we find in going over the literature reports such as those of Dale, in which he claims that adrenalin causes contraction of the gall bladder, reports such as those of Westphal, who worked upon rabbits and found that the gall bladder dilates after the use of adrenalin but contracts if

pilocarpine has been used before the adrenalin is used, and reports such as those of Houssay, so widely quoted, in which the gall bladder was found to dilate after adrenalin; and Dr. Necheles' results themselves are not entirely uniform in this respect. I believe he stated that the gall bladder contracted seven times after adrenalin and dilated once and once the result was indeterminate.

I think divergent results such as these are probably due to the fact that there are individual and species variations in the responses to these drugs, and that the tonus of the gall bladder at the time the drug is used probably has some bearing and also that different dosages of the same drug can probably cause different results.

Dr. Necheles feels that the clinical application of this work is in the perfection of some different motor meal for cholecystography. I believe he thinks that adrenalin could be used. We know that there are times when disturbances of the gastro-intestinal tract can cause improper emptying of the gall bladder after the giving of a fat meal; however, that probably does not occur very often and I think it is interesting to observe that Dr. Necheles uses fats as a control for the study of the effect of various drugs and has found a much higher response in contraction of the gall bladder to olive oil than he did to a substance like adrenalin.

It is also true that in patients with gall bladder disturbances, having cardiovascular disease, we might not feel it safe to use adrenalin. I feel, in closing, that there is one question which should be asked, which is not within the scope of the paper to answer, and that is whether or not failure of the gall bladder to empty, after the giving of the motor meal, has much clinical significance. If the gall bladder visualizes normally by cholecystography, and contains no stones, does the fact that it is slow in emptying after a motor meal is given, necessarily mean that the gall bladder can be responsible for the patient's symptoms? Personally, I am not convinced that the question is answered in the affirmative, but I think that a complete survey of that problem is a clinical corollary of any discussion of motor function of the gall bladder.

DR. ANDREW C. IVY (Chicago, Ill.): Mr. President, Ladies and Gentlemen: I should like to ask Dr. Necheles how many drugs he assayed on the same dog during the same day, or what were the periods between the administration of the various drugs to his subject. I raise that point because recently Dr. Doubilet and I have been studying the relation of the pressure in the gall bladder to the response to a threshold or a uniform dose of cholecystokin, and we have found that the pressure in the gall bladder determines the response. This curve (using the blackboard) illustrates our results.

The maximum response is obtained with a pressure in the gall bladder of four and a half to five and a half centimeters of bile pressure. If the pressure in the gall bladder is too low, we either get no response or a slight response. If the pressure in the gall bladder is quite high, we get either a slight response or no response.

This simply means, that optimum tension-length relationship exists in smooth muscle for an optimum response to a standard stimulus. This is true of smooth muscle whether it be in the nictitating membrane, the intestine, or the gall bladder. A distended gall bladder may empty slowly in response to the Boynton meal, because the intra-gall bladder pressure is too high or too low, as well as because of disturbances of the sphincter of Oddi, etc.

So, the point of my question addressed to Dr. Necheles is that if he injected some drug like morphine, which tends to make the gall bladder contract, it might raise the pressure and, if he shortly injects some other drug, the response that he gets to the second drug may be modified by the action of the first drug. In making our studies, we had to permit an hour, sometimes, to elapse between the applications of cholecystokin so as to permit adjustment of the gall bladder.

In regard to cholecystokinin, we can make a good preparation routinely, which is non-toxic in dogs and will make the gall bladder contract and evacuate, but we have not made a preparation which we would recommend for routine use in human beings.

If someone would supply me with a good hard-working organic chemist, I could promise to produce a cholecystokinin which could be injected routinely in human beings, and possibly a good gall bladder function test would be the result, in that we would be applying by intravenous injection, a standard stimulus. Egg yolks and cream by mouth, because of the variable factors pointed out by Dr. Necheles, do not constitute, necessarily, a standard stimulus.

We crystallized secretin recently, and the same can be done for cholecystokinin, with time and the assistance of an organic chemist.

DR. ARTHUR J. ATKINSON (Chicago, Ill.): It isn't surprising that Dr. Necheles in studying the effect of morphine on the gall bladder of dogs obtained results contradictory to those of other observers studying the gall bladder of man. Morphine is a powerful centrally acting emetic in the dog and very small doses produce nausea and vomiting. This central action of morphine will mask and disturb the gall bladder function in the dog.

I should like to ask Dr. Necheles how often he observed vomiting following the use of morphine in the dog.

DR. HEINRICH NECHELES (Chicago, Ill., closing the discussion): One of the reasons why we tried to find a substance that would contract the normal gall bladder was that a number of our patients that were given a milk-cream meal were allergic to milk; in these patients a normal reaction to the motor meal could not be expected.

We are also working on the question whether there may be such a thing as an allergic gall bladder, by adding the offending food to the motor meal; for instance, when we knew that a patient was sensitive to milk, we replaced the milk-cream motor meal by egg yolk or olive oil, and when we then added some milk and cream, we got different reactions.

As to the question of Dr. Tumen, the main thing that strikes me is whether a slow or delayed emptying of the gall bladder following a motor meal means anything. Yet it seems that a number of gall bladders are taken out for

that very reason, and I think this point should be important enough to be considered.

In answer to Dr. Ivy's question, we usually tried only one drug a day, and we did not use the dogs every day, but two or three times a week. We were well aware that a number of drugs produce a condition of the gall bladder which will last for a considerable period of time, e.g., like that following mechohyl. The gall bladders did not respond normally to olive oil afterwards, sometimes for two or three days or for a week.

We have also tried a number of drugs in succession, not to find out the effect of the individual drugs (which we had tried before) but to see whether one drug would influence the other; I have not gone into this because the results were too uncertain, but we took care of this point, of course, in our experiments.

I realize that like in the heart muscle and other musculature, there is a relation between the length and tonus of the muscle fibres and the reaction to drugs or to other stimuli. In our control experiments the diameters of the gall bladder did not vary much, and we are well aware of the importance of this fact.

From Dr. Ivy's publications I had the impression that some preparations of cholecystokinin, contracted the duodenum more, and others less, or not at all.

Dr. Doubilet's question is how completely the gall bladders emptied in our experiments. Of course, we had not observed the gall bladders *in situ*. We don't know whether they collapsed completely. We have given adrenalin intravenously and intramuscularly, and we got contractions of as much as 20 millimeters. Whether that means that the gall bladder folds up, as we frequently see it in acute experiments, I do not know, because we did not want to interfere with normal conditions.

Answering Dr. Atkinson's question as to the effect of morphine, we used doses between five and twenty milligrams which, for the dog are very small and which usually do not produce vomiting. From experiments with apomorphine not reported here, we know that vomiting affects the gall bladder.

I want to end by saying that the main thing I wanted to report today was the use of the new method in the trying out of drugs in what I think are rather ideal experimental conditions.

The Problem of Gall Bladder Infection

By

MARTIN E. REHFUSS, M.D.

and

GUY M. NELSON, M.D.

PHILADELPHIA, PENNSYLVANIA

THE gall bladder problem has crystallized along three lines of investigation, namely the question of stasis, the study of chemical or metabolic factors and the problem of infection. Many observers believe that the first question centers around or follows the metabolic or infective problems. As interest grows in the various metabolic factors producing alterations in bile, it becomes more and more apparent that an exciting factor must be present. From almost every method of approach the infective problem is the underlying one which demands solution. If that problem is solved, the other problems become more readily understandable.

Several years ago, we presented evidence to show

that chronic cholecystitis, in every way similar to that found in man could be produced in laboratory animals. Since then by varying the technique and by a more difficult method, we have finally attained a point where the evidence is not only complete, in our judgement, but where the associated phenomena are similar to those encountered in the human subject.

Let us briefly review this evidence, craving your indulgence while we review the work which has led to these studies:

1. Testimony from the operating table.

In an attempt to ascertain the incidence of infection we gathered the statistics from over 4395 gall bladders

Fig. 1. Type of rare intestinal lesion or colitis produced by antigen No. 7. Upper—normal bowel; lower—diseased bowel.

removed at the operating table, which were submitted to subsequent bacteriological study.

A critical analysis of 2162 cases of gall bladders removed following cholecystectomies, reveals the fact that in about 45% positive cultures were obtained. A little less than one out of every two gall bladders removed on the operating table were infected. The evidence in the remaining group of cases would suggest that a certain proportion of the remaining group had undergone such pathologic changes as one ordinarily associates with transient or even well marked infection at some previous point in the cycle evolving in gall bladder disease. Certainly the destruction of the mucosa, changes in the muscularis and submucosa are those which we have been able to demonstrate in our animals. For that reason, we believe that a bacterial lesion may induce organic changes and in the subsequent periods become entirely sterile. Thereby the conception that bacterial changes in the organ may completely subside or disappear is compatible with some of the pictures encountered in the sterile but incapacitated gall bladder.

The testimony from the operating room is even more important because it incriminates not one organism but a variety of organisms associated with chronic gall bladder disease. These organisms belong to the staphylococci, streptococci, typhoid colon groups and the anaerobic group. There is no single group in which one organism alone is mainly responsible or associated with gall bladder disease. For that reason, we began our work nearly 8 years ago by using bacterial antigens from various sources. These antigens were selected because they were similar to those encountered in the gall bladder on the operating table.

From these studies it was apparent that no one organism was responsible, but that under appropriate conditions. It was possible to reproduce gall bladder disease with antigens varying widely both in their morphological characters and their derivation. Actually, at Frankford Research Laboratory we have used 105 antigens in all and for all sorts of work, nearly 1500 animals. We have been familiar not only with the behavior of the rabbit, which was the animal used, but also with the nature of the lesion produced.

Our present work, which was conducted by Dr. Nelson, was an attempt to improve the methods previously used. Elsewhere, and in detail we hope to consolidate this work which has covered an enormous

amount of material, daily charts, which were kept, followed the condition of each animal. Those of you who are interested can see this data, covering several large volumes recording the progress of each of these animals for the last eight years. Time prevents us from entering into the details of such studies except to point out that only by following such a procedure was it possible to follow these animals from the first stage of inoculation to the final autopsy studies. The early studies consisted in the introduction at measured intervals of small doses of the antigen intravenously. After several series of studies were made, it became apparent that the only successful way in which this work could be carried out was by repeated small injections over very much longer periods of time, capable of inducing, as registered by charts, definite changes in the animal. For this reason, the last series of 109 rabbits represents the nearest approach to a technic which in all probability resembles the disease found in the human subject. This series, received in all 1818 separate injections or 16.6 as the average number given to each animal. The number of injections varied from as low as 2 to as high as 51, the largest number of injections administered to any animal. These animals were observed over many months. Without submitting details, the organism, a nonhemolytic streptococcus from the bowel, produced lesions of the gall bladder in 21% of the first group. In the last series, it produced gall bladder disease in 48 animals or 44% of the entire lot and in 5 further instances the results were doubtful. In other words, by modifying the procedure and adopting a method which more nearly approached the process which may occur in man, we were able to obtain evidence of gall bladder disease in nearly one-half of these animals. These changes were gross and microscopic representing in cross-section practically every form encountered in the human subject, from thickening, swelling, even empyema and perforation. Gross changes in the bile were noted in 40 animals and the cultures were recovered from the bile in 14 of the animals.

These studies illustrate that it is possible to reproduce chronic gall bladder disease in laboratory animals like the rabbit by a bacteriologic antigen from a human source (large bowel). The organism can be recovered and the disease reproduced in similar fashion. This particular strain has gone through a large number of animals, without losing its essential

Fig. 2. Extensive joint lesion produced by antigen No. 7.

Fig. 3. Valvular heart disease produced by antigen No. 7.

character or its striking power. Furthermore we noted kidney disease, heart disease, and joint disease as the commonest associated lesions. This is interesting because in the experience of one of us 31% of 908 gall bladder histories suggests muscle, nerve, or joint involvement and in 39.6% there was some evidence to suggest impairment of the cardiovascular system. This association is gaining increasing recognition from clinicians. We believe on the basis of our observations that the same etiologic factor which strikes at the gall bladder will affect the kidneys, heart, joint or other organs in the body. Only in this way can we explain the associated disease so often found. We believe furthermore that antecedent infection is essential to gall bladder infection, most frequently in the sinuses, throat and bowel.

The problem of gall bladder infection is therefore first the recognition that chronic cholecystitis can be produced in healthy animals, from strains isolated from the nose, throat, teeth and bowel, etc. In our experience, the most powerful antigen was a bowel strain. For this reason we believe that it is necessary in every case to survey these antecedent or associated foci.

Furthermore there is in the study of a gall bladder problem much which indicates the underlying infectious nature of certain types of this disease. The fact that it is likely to occur after an acute infection, the fact that attacks may follow obvious flare-up of an antecedent or coincident focus of infection in the body and the strong tendency for a certain form of chronic cholecystitis to show seasonal exacerbation, particularly in the spring and fall. All of us who have handled many of these cases recognize the tendency of a certain group to show active signs of inflammation for periods of time. Furthermore in the infectious form there is abundant evidence to show that there are systemic manifestations as well as the local evidence of the disease. Many of these patients are chronically tired, secondary anemia is evident, 31% show some form of rheumatic phenomena, three out of four have a disturbance in colon function, a condition which is conducive to disturbances in the hepato-biliary tract, a vicious circle which the clinician is quick to recognize and which he must control. Associated diseases in the renal, cardiovascular and even endocrine systems is by no means uncommon, aiding in the discomfort of the patient and creating other vicious cycles resulting

in physical inefficiency. The individual with an actively infected gall bladder is usually a tired patient, inclined to insomnia, inclined to fatigue with unmistakable signs of deterioration in physical efficiency.

Physical examination reveals one of the most valuable single clinical signs, namely tenderness over the affected organ. This sign is of vital importance when clearly unilateral and clearly defined over the gall bladder and may supersede all other evidence even when cholecystography and duodenal intubation reveal no evidence in support of such a lesion. We believe no sign is more important than this, but it must be remembered that tenderness over the gall bladder depends upon the position of the organ. As the cholecystographic studies have shown, the organ may be anywhere in the right abdomen and in one case of ours it was in the midaxilla where the tenderness was actually shown to be. Tenderness we believe to be the outstanding sign of the inflamed and, in most cases, the infected gall bladder and disappearance of tenderness, the best single sign of its abatement.

We cannot deny the great values of cholecystography as an aid to diagnosis. It is an objective, anatomic diagnosis, yielding information regarding certain valuable points in the physiological behavior of the organ, but it is far from being a perfect answer to the question of early gall bladder disease. If disease alters the outline or form, interferes with the entrance of the dye, alters its concentrating power or introduces foreign bodies like stone, the evidence of such disease should be available by cholecystographic study. But we are convinced that a normal cholecystogram is comparable with even advanced disease of the gall bladder as we have had occasion to demonstrate. Furthermore by modern reinforcing methods, the interpretation of the quality of the shadow is often difficult. You have, we are sure, seen tender gall bladders which revealed a perfect shadow and we have seen such a gall bladder operated upon which was markedly diseased. For that reason, we believe that such studies must be interpreted with caution and that we must guard against the conception that a normal outline and shadow precludes gall bladder disease. We all know today how frequent are mucosal changes and disease in the gastric wall as revealed by modern endoscopic methods, when X-ray studies apparently revealed a normal organ. We believe that such is often the case in biliary tract disease and, if we had a normal cholecystographic study and a definitely tender gall bladder, we would incline toward the diagnosis of cholecystitis.

From a somewhat different angle, the same criticism extends to the data yielded by duodenal intubation. There is no better method for investigating the physiology of the biliary tract, for detecting alterations in the color sequence and for ascertaining evidence of mucosal disease as shown by the cytology of the bile

Fig. 4. Extensive renal changes produced by antigen No. 7.

Fig. 5. Rather rare hemorrhagic erosions of the stomach produced by antigen No. 7.

fractions. Here again, operative statistics and our own experimental studies show how difficult it is to appraise the bacteriologic evidence afforded by even the most careful segregation. Operative statistics show infection of bile in only 26-28% of cases and even then the organisms were not always similar to those in the gall bladder wall. Furthermore the gall bladder wall may be definitely infected with no evidence of infection in the bile specimens and finally extensive involvement of the mucosa may occur with no evidence by exfoliative data to suggest either the nature or the extent of the underlying lesion. That biliary tract disease does cause in many instances, an alteration of the color sequence, betray its evidences by changes in the cytology of the bile and even convey the organisms responsible for disease is undoubted. But we maintain that gall bladder disease does occur where any or all of these factors are lacking.

We have presented but a short resume of our studies of some eight years, on selected strains and particularly one selective strain. We believe that if other strains were subjected to similar fashions they would probably reveal similar data. With this particular strain we were able to reproduce in laboratory animals chronic lesions in every way similar to those encountered in man. Furthermore we believe that the evidence afforded by a careful clinical study would reveal that infection plays a large role in its evolution.

As we see the problem of chronic cholecystitis, the handling of such a problem depends upon a precise diagnosis. The diagnosis depends upon the history, physical examination, cholecystogram and careful duodenal studies. The history should indicate the extent, duration and type of lesion and it should include a cross-examination regarding the existence of other foci of infection, the control of which is so necessary in this type of case.

The physical examination should ascertain the degree of sensitivity and careful localization of physical phenomena. Again, the physical examination should seek to demonstrate the possibility of any other focus of infection. Infected throats should be bacteriologically surveyed. All teeth should be X-rayed and within the last few years we have cultured duodenal contents, sigmoid smears and catheterized urinary samples. Any antecedent focus of infection should be considered from the standpoint of eradication or control and also

as a source of a possible bacterial antigen. For many years we have used vaccines and filtrates, at times with unusual success. Our method of preparing these vaccines is somewhat different from the accepted routine and most of the filtrates must be markedly diluted. A number of our patients show an allergic skin reaction to various strains of carrier organisms. We prefer not to discuss, in this contribution, the details regarding this type of therapy.

There is no doubt but that the vitamin problem is important for one who is to be put on a diet for a long time. This is particularly the case regarding Vitamins A and D, the fat soluble vitamins and D-1. Active gall bladder patients notoriously show an intolerance for the ordinary preparations of the fat soluble vitamins. They frequently produce regurgitation, flatulence or even active indigestion. For that reason, we have insisted upon the safest of fats, butter fat, and as complete a diet as it is possible for these patients to handle. The building up of the patient requires all those dietetic, hygienic and psychological helps so necessary to the chronic invalid. We can point out, however, from these studies, that the care and control of the colon is a vitally important part of the handling of any gall bladder case. Three out of four cases have colon dysfunction and the question of colon infection is certainly even today, a relatively unexplored field. In a later communication, we hope to give in detail the results of these studies as well as those which have been used in an attempt to control the experimental lesion.

DISCUSSION

DR. WILLIAM A. SWALM (Philadelphia, Pa.): I should like to ask Dr. Rehfuess one question. We have been very much interested in the etiology of cholecystitis. He has had a marvelous opportunity here of saying whether he believes the infection might in a majority of the cases be mucosal in origin, submucosal, with its rich vascular network, or serosal. Of course, the muscle, I suppose, is unimportant in the majority of the cases. If he caught them early enough, did he open up the gross specimens and try to study that point?

DR. IRVING GRAY, (Brooklyn, N. Y.): The authors are to be congratulated upon their intensive studies. During the past year Dr. Walzer and I working with the Macacus Rhesus monkey, have demonstrated that antigen is absorbed from the gall bladder. We have sensitized the skin and the mucous membrane of the intestinal tract in the rhesus monkey by means of passive transfer. Several days later the specific antigen was introduced into the gall bladder. Within a short time (approximately five minutes) a local allergic reaction developed at the sensitized sites. We have also sensitized the mucous membrane of the gall

Fig. 6. Extensive chronic cholecystitis produced by antigen No. 7.

Fig. 7. Extensive mucosal changes in chronic cholecystitis produced with antigen No. 7.

bladder by passive transfer and a few days later introduced the antigen intravenously. There developed at the sensitized site in the gall bladder a local allergic reaction. The changes in the mucous membrane were similar to those which occurred in the mucous membrane of the ileum and colon of the human being. Moving pictures of the allergic reaction as it occurs in the mucous membrane of the gastro-intestinal tract in humans were shown before this association last year.

I should like to ask Dr. Rehfuss, whether he has any method or means of determining if the changes that occurred in the heart, in the joints and in the kidneys of the rabbits which he studies were due to the absorption of antigenic substance from the infected gall bladder. If it could be shown that the injection of streptococci first produced cholecystitis in the rabbits and that changes subsequently occurred in the other organs, one could reasonably assume that antigen was absorbed from the diseased gall bladder.

Our experimental studies on the rhesus monkey indicate that not only can the gall bladder be the seat of an allergic reaction but also that antigen is absorbed from this organ.

DR. HEINRICH NECHELES, (Chicago, Ill.): In connection with the work that I reported, I should like to make a suggestion to the speaker. In the rabbit and the dog, Dakin's solution given intravenously in small doses, is known to produce a slight cholecystitis. We are doing this in our experimental animals and then are trying the response of the various drugs tested on the normal gall bladder. It is an old question whether an infection of the gall bladder begins in a normal or in a damaged organ.

Fig. 8. Empyema of the gall bladder produced with antigen No. 7.

Fig. 9. Cross-section typical case of chronic cholecystitis showing involvement of all the walls.

The use of Dakin's solution, of course, is rather crude experimental technique, but one may possibly be able to simulate disturbances of the gall bladder produced by changes in adjacent organs. By making the gall bladder a focus of lessened resistance a greater percentage of "takes" may be produced when bacteria are injected into these animals.

DR. MARTIN E. REHFUSS (Philadelphia, Pa., closing the discussion): The best way I can answer these things—I should like to answer them in turn, but I will begin with Dr. Boyd's remarks. He reported the experiments of Wilkie and other experimenters. In the first place, this is chronic cholecystitis, not acute cholecystitis. This lesion has taken over two years, in some instances, to produce. How much does a man need to prove chronic cholecystitis? Where do you get the muscle thickening? I have shown only a few slides because I couldn't show all I wanted. How much information and evidence does he need to be satisfied? One of these experimental gall bladders is ten and twelve times the normal thickness. This is not acute cholecystitis that the experimenters have been talking about. We went through that. I saw the work in Rochester and went carefully over Wilkie's work, but the only way to do this is to do what we did, and when somebody spends five years, as Nelson and I have done all together, working day after day, and produces this sort of thing, or fails to produce it, I will believe the sort of testimony they may bring.

I, for one, am absolutely convinced. We selected the rabbit because we are familiar with it. The dog wasn't selected because we couldn't use the dog. Even with our space we couldn't manage it from a practical angle.

Now the question comes up, as Dr. Swalm has mentioned, the questioned of the etiology of gall bladder disease. When he speaks of etiology, I presume the cause of it—he means what way has this particular type of thing come about. When I am talking about chronic cholecystitis, I can talk only of the particular antigen we have used.

Streptococcus viridans and some other strains do hit the gall bladder and others do not. The same thing is true regarding the hemolytic group. In this particular strain I can show slides showing every part of the gall bladder wall involved, the mucosa, the submucosa, and muscularis, and I should be glad to demonstrate others if he will come out to the laboratory.

Regarding the other questions, the point is, here is a culture in an animal, the production of a disease, the obtaining of a culture again, and the reproduction long enough to be reasonably certain these things go together; and the other striking thing is that this antigen not only hits the gall bladder but also other organs, particularly the joints, and the heart, and kidneys. Clinicians are waking up to the fact that chronic gall bladder disease is frequently associated with cardiovascular or nerve and muscular disease.

In the cases I diagnosed in eight years, they had nerve, muscle, or joint involvement in some part of their history, in 31% of cases and some did have active arthritis. That is what these animals do under similar circumstances.

Thirty-nine per cent of our patients with chronic gall bladder disease had some sort of heart consciousness, and they are beginning to talk of the association. Here is the only place I am going to speculate. We believe that the same underlying etiologic factor hits both places at once, not the gall bladder first, and heart and vascular system later, but probably all these things at one time, and there is a shift in relationship. We see that shift definitely in animals. We stop our injections and the phenomena clear up. Again we find gall bladders that have no definite bacteria but have been damaged.

Someone said, "How about the human gall bladder?" Well, study the literature and find out whether it has been cultured; secondly, whether the culture was introduced into animals, and you will find the evidence in the literature is very incomplete. Some men give every detail and others simple, sparse information as to the finding of bacteria, but there are at least two thousand cases in the literature where it has been worked out very carefully, and in those two thousand cases, only 45 per cent, were found infected.

How about the sterile gall bladders on the operating table? The pathologist reports damage to the mucosa and reports changes in the submucosa and muscularis. Where did the changes come from? Did they come from metabolic disturbances, I ask you. Perhaps they did. Perhaps it is possible with Dakin's solution, but neither you nor I have ever taken enough of it to guarantee we will get a cholecystitis. In closing, the fact that you don't get a culture on the operating table is no evidence whatsoever that there hasn't been an antecedent infection. When we inject our animals and stop, the antecedent infection disappears, but the damage is there; therefore, if I may have digressed, I have been doing a great deal of thinking on this subject and until we can strike at the underlying factors that have induced the changes in the gall bladder, I do not believe we can make much progress. I believe it is your business and my business, as internists to work out a combination of affairs which will cause subsidence of gall bladder infection, and I am one of those who believes that it does take place.

The Relationship of Lesions of the Cystic Duct to Gall Bladder Disease*

By

W. H. COLE, M.D.

and

L. J. ROSSITER, A.B.

CHICAGO, ILLINOIS

ALTHOUGH attention was called to the relationship of lesions of the cystic duct to cholecystic disease many years ago by Schmieden and Rhode (1), Seelig (2) and others, this feature of cholecystic disease, particularly partial obstruction of the duct, in the absence of stones has received very little attention since then. During the past few years the author has observed numerous patients with typical history of gall bladder disease who were cured following cholecystectomy although very little evidence of inflammation was noted in the body of the gall bladder. This is, as a matter of fact, an old observation. Many of these gall bladders contained no stones. The lack of correlation between symptoms and the amount of pathologic change in the gall bladder has been generally recognized for decades. While conducting a study of this relationship, the authors noted that not infrequently the fundus showed very little, if any evidence of disease, but sufficient pathologic change was noted in the cystic duct to explain the symptoms. Most of these lesions encountered were of the type which would lead to obstruction of

the duct particularly if a local temporary disease would induce edema at that point. The absence of severe pathologic change in the wall of the gall bladder would lead one to suspect the possible presence of Westphal's (3) biliary dyskinesia as popularized in this country by Ivy (4), Walters (5), Best (6) and others. Unfortunately the gross appearance of the fundus of the gall bladder may be similar (i.e. frequently almost normal) in biliary dyskinesia and obstruction of the cystic duct. Differentiation then could only be made by examination of the duct. Many of the cystic duct lesions will not be discovered until after cholecystectomy when the duct can be opened. If the symptoms are caused by lesions of the cystic duct cholecystectomy will relieve the patient, whereas in at least one of the types of biliary dyskinesia, removal of the gall bladder is apt not to alleviate the symptoms.

ANATOMY AND EFFECT OF PATHOLOGIC PROCESSES ON THE PHYSIOLOGY OF THE CYSTIC DUCT

There is probably no organ in the body which is so subject to variations or anomalies as is the cystic duct.

*From the Department of Surgery, University of Illinois, College of Medicine, the Illinois Research and Educational Hospital and the State Department of Public Welfare, Chicago.

Fig. 1 Drawing showing cystic duct (before and after opening) after cholecystectomy in Case 4. Cholecystogram revealed no shadow. There is an angulation of the cystic duct with a marked fibrosis of its wall as shown in Fig. 2.

These variations include all features such as size, length, shape, etc. Although it is usually stated that the cystic duct is "S" shaped, Mentzer (7) found that in a study of 612 autopsy cases this shape was noted only in 19. In 41 instances the duct was curved rather sharply and flexed upon itself. It is agreed however that the duct is not a direct continuation of the neck of the gall bladder, but leaves from the side. Variations in the cystic duct with particular consideration of the valves of Heister have been very ably discussed recently by Lichtenstein and Ivy (8). Most anatomy books describe the valves of Heister as being arranged in a spiral fashion down the lumen of the cystic duct, but in our study of pathologic gall bladders as removed at operation, very seldom indeed was a duct encountered with spiral valves. Whether or not the loss of the spiral shape of the valves per se has anything to do with gall bladder disease is a question which the present study does not answer. However, certain anomalies as will be described do appear to have a definite relationship to cholecystitis. Experiments performed by Lohner (9) suggested that the valves impeded the flow of fluid from the gall bladder to the common duct more than the flow in the reverse direction. However, Johnson and Brown (10), Mentzer (7) and Lichtenstein and Ivy (8) were unable to demonstrate any significant difference in the pressure required to force fluid through the duct in the two directions. The latter authors concluded that the function of the valves is to prevent distension or collapse of the cystic duct in case sudden pressure changes occurred in the gall bladder or common duct.

The wall of the cystic duct is composed of three layers of smooth muscle fibers similar to the gall bladder. A few authorities are of the opinion that there is actually a sphincteric action at the upper portion of the cystic duct and that a spasm of this region, with consequent obstruction to proper flow of bile, might exist under pathologic circumstances. At the present time however there is insufficient evidence available to

support the theory that an actual spasm with sufficient action to produce obstruction could exist. The acute bend of the neck of the gall bladder and a fold of the mucous membrane which is frequently present at that point may at times act in an artificial way as a sphincter.

PATHOGENESIS AND RELATIONSHIP OF CYSTIC DUCT LESIONS TO SYMPTOMS

It is generally agreed that normal Heister valves do not offer significant obstruction to the flow of bile either into or out of the gall bladder. When congenital or inflammatory lesions constrict or impinge upon the lumen of the duct it is obvious that a certain amount of obstruction will be produced, particularly when the impingement on the lumen is increased by attacks of acute inflammation which might involve that area. It is well known that acute or subacute inflammation occurs about the gall bladder in attacks varying greatly in frequency and intensity. Obviously if the obstruction is complete and extends over a period of days or weeks hydrops or empyema will result. An important feature in the clinical significance of lesions of the cystic duct lies in the fact that many of them are congenital, representing anomalies of the cystic duct or valves of Heister, and produce no symptoms until late adult life when inflammatory processes are known to be most prone to manifest themselves. Edema at the point in question (e.g. kink in the duct, or transverse fold of Heister) will then produce significant obstruction which may or may not be complete. This edema might subside rapidly, but if the inflammation

Fig. 2. Photomicrograph of section of wall of cystic duct in Case 4. The wall is greatly thickened and the muscle is almost completely replaced by fibrous tissue. Since the body of the gall bladder was so slightly diseased it appears that the explanation of the failure to obtain a shadow on cholecystogram lies in the obstruction produced by thickening of the cystic duct and the angulation.

Fig. 3 Enlarged photograph of the cystic duct in Case 3. Note the maze of fibrous strands located in the neighborhood of the folds of Heister. These strands are probably congenital and inflammatory in origin, and represent the only explanation found of the patient's symptoms which were so typical of gall bladder disease. This maze of fibrous strands possibly acted as an obstruction to emptying of the gall bladder shadow as shown in Fig. 4. The most scarring and obstruction is noted at the distal end of the duct.

was sufficient to produce ulceration the resultant scar might be sufficient to produce a partial obstruction even without the aid of subsequent inflammation with its incident edema. Recent theories regarding the etiology of gall stones indicate that a certain group (particularly cholesterol) may form in the gall bladder, because of abnormal metabolic factors in the absence of any disease of the gall bladder itself. Any of these stones when small might produce edema and ulceration of the cystic duct while passing down the duct and be the primary cause of ulceration and scar formation. It must be remembered that an acute inflammation may develop in a previously normal duct and likewise be responsible for the development of scar and adhesions.

It is obvious that if the obstruction of the cystic duct is present in a gall bladder whose wall is sufficiently normal to concentrate bile, the obstruction will be more apparent because the bile will be much more viscid and pass through the obstructed area less readily than hepatic bile. As a matter of fact, the pain in the patients in this series was perhaps most acute in the group of patients whose gall bladders responded with normal density in cholecystograms, but in which emptying was delayed as demonstrated by response of

the gall bladder shadow to the fat meal. Since various factors such as adhesions, scar formation and stones are known to produce complete obstruction, it appears quite logical to assume that a partial obstruction would likewise be common, and perhaps even more common than complete obstruction. Since it is known that partial or complete obstruction of the lumens of other communicating channels in the human body occur rather frequently, is it illogical to conclude that the cystic duct may be similarly involved? It is extremely difficult to prove by experimental methods that partial obstruction of the cystic duct exists to any significant extent because after the gall bladder is removed, the relationship of the pathologic lesion to its points of fixation, etc., are totally destroyed thereby invalidating the results. Tests performed with the gall bladder *in situ* before removal of the organ might yield informative results but such procedures would be time consuming and be difficult to justify while the patient was under an anesthetic. It is a well known fact that when the gall bladder is straightened out emptying of the organ is greatly facilitated. Adhesions which are so prevalent about the cystic duct would almost of necessity interfere with straightening of the gall bladder even with the most striking muscular effort, and in that way alone interfere with emptying.

In 1927, Lyon and Swalm (11) called attention to edema of the cystic duct as a factor in obstruction of the duct and production of symptoms designated as cholecystic in origin. They spoke of this condition as catarrhal inflammation and recognized the fact that after the inflammation had subsided normal function of the gall bladder, as determined by cholecystography, might be regained. For this reason surgery must be advised much more cautiously in this type of lesion. It would appear that acute inflammation of the cystic duct would be a frequent lesion, particularly since the lymphatics from the various abdominal organs pass so near the duct and frequently are contiguous with it. The frequent presence of dense adhesions about the cystic duct supports this contention. It cannot be determined how frequently inflammation in the cystic duct spreads to the body of the gall bladder or vice versa. Experiments are being started in this laboratory in an endeavor to obtain information on this point. It is likewise difficult to determine through which anatomical structure (i. e. mucosa or serosa) the inflammation might spread. Evidence is already available, however, to indicate that chronic obstruction of the cystic duct may result in pathologic processes on the gall bladder side. Phemister and associates (12) have called attention to the development of calcium stones and calcification of the gall bladder wall in the presence of chronic obstruction of the cystic duct. It is obvious that an obstruction of the cystic duct, though incomplete, would result in stasis. Many authorities consider that this is an important factor in the development of gall bladder disease including the development of stones (Naunyn, Asehoff and Baemeister). It is possible that partial obstruction, particularly when temporary, may be associated with a more extended effort on the part of the gall bladder to empty itself. Whether or not this increased activity has anything to do with the production of pain cannot be determined decisively.

Up to the present time there is no unanimity of opinion as to what pathologic factor is responsible for the various symptoms observed in cholecystitis.

Fig. 4. Cholecystogram showing response of the shadow to the fat meal. There is such a delay in emptying of the gall bladder that a dense shadow still remains 5 hours after the fat meal.

Fig. 5. Drawing of the cystic duct in Case 6. A large fibrotic nodule was found at the location of the 1st fold of Heister, and probably represents a lesion implanted on it. This lesion was not annular, and for that reason probably did not act as a very significant obstruction. Cholecystogram showed no shadow. There was moderate thickening of the gall bladder wall, and stones were found in the gall bladder and common duct. (See Fig. 6).

Certain features are apparent however. For example, when a stone becomes lodged in the cystic duct or is being passed through the cystic duct or common duct, the pain which is so typical of gall bladder disease is reproduced. It is equally well known that a patient may carry stones in the gall bladder for years without the presence of any pain whatsoever. Although more difficult to prove, it appears that if stones in the common duct remain in the duct without approaching and blocking the sphincter of Oddi, pain may be very insignificant. It is probable that infection of the gall bladder wall itself does not produce severe pain—particularly of the colicky type. The fact that cholecystogastrotomy or cholecystoduodenostomy, which is usually associated with considerable infection of the gall bladder wall and liver (Lehman, Horsely and others), is rarely associated with pain in the right upper quadrant, (though may be associated with dyspepsia) supports the contention that the severe pain in gall bladder disease arises from a site other than the gall bladder wall. Lichtenstein and Ivy (8), Womack (13) and others have called attention to the presence of numerous nerve fibers and ganglia in and about the cystic duct, implying that lesions in this area might be painful. Obviously, the mere presence of numerous nerve fibers here does not prove that the cystic duct is a particularly sensitive spot but clinical experience supports this assumption in so far as it is well known that during the early stage of obstruction of the cystic duct by stone, the condition is commonly accompanied by severe gall bladder colic.

CLASSIFICATION OF OBSTRUCTIVE LESIONS OF THE CYSTIC DUCT

Complete obstruction of the cystic duct leads to hydrops or empyema of the gall bladder. These two conditions are frequent and are so well known that they will not be discussed here. However, we wish to call attention to the fact that in many instances no stones will be found in the ducts of patients with hydrops and empyema, indicating that the stenosis was presumably produced by scar resulting from an inflammatory process. The incidence of non-calculous lesions in incomplete obstruction of the cystic duct

will be much higher than in complete obstruction (i. e. hydrops and empyema) because the stone acting as a foreign body, would tend to increase the inflammatory process to a maximum.

The lesions capable of producing an incomplete obstruction of the cystic duct are numerous indeed. Most of them as listed below have been mentioned at various times in the medical literature by various authors. Generally speaking lesions of the cystic duct may be congenital or inflammatory in origin (rarely neoplastic) and may be secondary to changes in the wall itself or in the valves of Heister.

LESIONS RESPONSIBLE FOR OBSTRUCTION (PARTIAL OR TEMPORARILY COMPLETE) OF THE CYSTIC DUCT

1. Stenosis produced by surrounding adhesions. (Case 1)
2. Stenosis produced by a thickened wall.
 - (a) Due to acute inflammation.
 - (b) Due to diffuse fibrosis. (Case 4)
3. Congenital or inflammatory twists or kinks. (Case 2)
4. Congenital or inflammatory lesions involving valves of Heister.
 - (a) Fibrous strands. (Case 3)
 - (b) Local deposition (nodules) of fibrous tissue. (Case 6)
 - (c) Stricture due to scar.
 - (d) Valve-like anomalies. (Case 5)
5. Stone in the duct. (Case 7)
6. Tension induced by enlarged liver.
7. Compression or filling defect due to tumor or lymph nodes.
8. Obstruction due to anomalous hepatic or cystic artery.

1. *Stenosis produced by surrounding adhesions.* This is perhaps encountered more frequently than any other lesion. By no means are all of them obstructive in spite of the fact that the duct may be buried in adhesions. This group is illustrated by Case 1, a woman who had a cholecystostomy one year previously with recurrence of symptoms after a few months. The cystic duct was buried in dense adhesions and was so small that it is difficult to see how bile, particularly viscid bile produced by a gall bladder with normal concentrating ability, as was present in this patient (see Fig. 8) could pass through the compressed duct.

2. *Stenosis produced by a thickened wall.* The wall of the cystic duct may become thickened by acute inflammation (i. e. edema, etc.) or by the deposition of fibrous tissue. Obviously the acute inflammatory process would be observed only when cholecystectomy has been performed for acute cholecystitis. If such an acute process were severe or recurred numerous times it is to be expected that an unusual amount of fibrous tissue would be deposited. This is what was found in Case 4 (see Figs. 1 and 2). This patient had severe pain in the right upper quadrant of 5 years duration. Cholecystogram showed no shadow. At operation the duct was rather sharply angulated, small, and its wall thickened. The thickened wall made the lumen very small indeed. The wall of the gall bladder in this patient was only very slightly diseased, implying that the stenosis of the cystic duct produced by the thickened wall may have prevented the entrance of sufficient bile into the gall bladder to allow the de-

velopment of a shadow on the cholecystogram even though the gall bladder itself may have been able to concentrate bile.

3. *Congenital or inflammatory twists or kinks.* Twists and kinks are quite commonly encountered at the operating table but seldom will one be able to differentiate between a congenital and inflammatory lesion. The presence of dense adhesions may point to an inflammatory origin but obviously the twist or kink may have been present before the adhesions were deposited and in fact may have been an important factor in the pathogenesis of the inflammation which resulted in the adhesions. The lesion is illustrated by Case 2, a woman having had a cholecystostomy performed twelve years previously. Attacks of pain in the right upper quadrant recurred after six years. The cholecystogram, as will be discussed later, revealed a shadow of normal density but was deformed and emptied only slightly after the fat meal. Operation revealed a few adhesions attached to the gall bladder, presumably resulting from the previous operation, but the wall was only very slightly diseased. The duct was sharply angulated and buried in dense adhesions. Here again it would appear that the stenosis of the lumen (as produced by the kink) was sufficient to interfere with the emptying of viscid bile which was presumably produced by her gall bladder as suggested by the cholecystographic shadow of normal density.

4. *Congenital or inflammatory lesions involving the valves of Heister.* In this group may be included obstructive lesions produced by fibrous strands, local

nodules consisting of connective tissue, stricture due to scar and valve-like anomalies. These may be congenital or inflammatory except that the latter group is most apt to be strictly anomalous.

Case 3, who was a woman complaining for fifteen years of pain in the right upper quadrant radiating to the back, had a gall bladder with a cystic duct obviously partially obstructed by numerous fibrous strands. (See Fig. 3). The cholecystogram revealed a gall bladder shadow of normal density but it failed to empty after a fat meal. (See Fig. 4). As might be expected the body of the gall bladder appeared practically normal grossly and microscopically. The maze of fibrous strands which are no doubt associated with the folds of Heister are so numerous that it is difficult to understand how bile could pass, particularly viscid bile from the gall bladder which was obviously still able to concentrate.

The gall bladder of Case 6, who had been complaining of severe attacks of pain in the right upper quadrant of four years' duration, had a large solitary nodule $\frac{1}{2}$ cm. in diameter located at the junction of the cystic duct and neck of the gall bladder at about the location of the first fold of Heister. (See Fig. 5). This nodule was composed solely of scar tissue, as shown in Fig. 6. The lumen of the duct was open sufficiently to suggest that the nodule would be obstructive only in the presence of edema incident to inflammation. Cholecystogram revealed no shadow. At operation stones were found in the gall bladder and common duct. The gall

Protocol of cases Illustrating partial obstruction of the cystic duct*

Case No.	Sex Age	History	Type of Pain	Cholecystogram	Op. and Path. Findings		
					Body of G.B.	Cystic Duct	Stones
1 A. F.	F 46	C'stomy 1 yr. ago. Relief 6 mos. Frequent attacks pain typical G. B. disease.	Usually colicky. Very little dyspepsia between attacks.	Norm. density. Very little resp. to F.M. Dense but smaller shadow after 3 hrs.	Slightly thickened. Few adhesions.	Stenosed. Buried in dense adhesions.	No
2 A. D.	F 38	C'stomy 12 yrs. ago. Relief 6 yrs. Recurring attacks pain R.U.Q. with lot vomiting.	Usually occurred as attacks of colic typical of G.B. disease.	Norm. density. Deformed. No evidence of emptying 1 hr. after F.M.	Wall about normal. Few adhesions previous op.	Sharply angulated. Buried in dense adhesions.	No
3 E. B.	F 46	Pain R.U.Q. 15 yrs. duration radiating to back. Vomiting frequent. Aversion to fatty food.	Severe. Radiates to back. Mild colic.	Norm. density. Still dense shadow 5 hrs. after F.M. (See Fig. 4).	Appearance about normal.	Fibrous strands (V. Heister) obstructing lumen (See Fig. 3).	No
4 S. W.	M 47	Disabling symptoms typical of G.B. disease. 5 yrs. dur. Jaundice 2 mos. shortly after onset.	Very severe and quite constant. Few attacks colic.	No shadow.	Few filmy adhesions. Wall gray, not thickened.	Buried in adhesions; angulated; wall thickened (See Fig. 2).	No
5 N. R.	M 37	Severe attack pain with vomiting 3 mos. ago. Dur. 6 days. Dyspepsia since. Fatty food reproduces pain.	Rather constant. Occasionally colicky.	No shadow.	Slight thickening.	Valve-like cuff at opening of cystic duct.	No
6 E. B.	F 37	Severe symptoms typical G.B. disease 4 yrs. dur. 2 short attacks jaundice.	Colicky. Occurred in attacks. Mild dyspepsia.	No shadow.	Moderate thickening.	Large fibrotic nodule at site 1st Heister fold. (See Fig. 5).	In G.B. and C.D.
7 C. S.	F 37	Frequent attacks severe pain R.U.Q. with nausea and vomiting 5 mos. dur. 1 attack jaundice at onset.	Severe colic in R.U.Q. occurring in attacks.	No shadow.	Normal fundus. Numerous small stones.	Stone encysted in cystic duct.	In G.B.

*All of the patients were relieved of symptoms by cholecystectomy, but were operated so recently that the permanency of cure cannot be determined. Case No. 3 was relieved of pain in the right upper quadrant but has gained about 50 lbs., and is now complaining of pain in the lumbo-sacral region and cardiac region.

Fig. 6. Microscopical section of the nodule projecting into the lumen as shown in Fig. 5. The lesion consists of connective tissue (C) in which a few muscle bundles (M) are interspersed, and appears to be the residue of an ulcerative process, possibly associated with the gall stones. In support of this assumption is the fact that the scar is densest at the mucosal side near the lumen.

bladder wall was diseased sufficiently to cast doubt as to the ability of the organ to concentrate, thereby making it difficult to tell whether the lack of shadow on cholecystogram was caused by an obstruction of the cystic duct or by disease of the gall bladder wall.

Strictures due to scar formation are undoubtedly common and probably account for the great majority of cases of hydrops or empyema of the gall bladder in which no stones are found.

Valve-like anomalies are probably congenital in origin and are quite frequent. Originally they were apparently large folds of Heister but became cup shaped because of the pressure exerted by viscid bile and concretions or stones from the gall bladder side. The fact that their concavity practically always faces the gall bladder suggests that they have acted as an obstruction to the contents of the gall bladder while being expelled through the duct. Case 5, a man aged 37, with pain of only three months duration, had a large well formed cup shaped valve-like fold at the junction of the cystic duct and neck of the gall bladder where the lumen was still 6 to 8 mm. in diameter. When filled this cup shaped fold, which extended all the way across the duct undoubtedly acted as a serious obstruction. Obviously, when collapsed, bile could enter the gall bladder without difficulty. If edematous it would obviously produce an obstruction in both di-

rections. Cholecystogram revealed no shadow, but it was performed a few days after an acute attack of right upper quadrant pain. Unfortunately, we did not get a later cholecystogram. Operation was not performed until several days later. On the assumption that his disease was of such short duration that recovery to a fairly normally functioning gall bladder may have taken place after the lapse of a few more weeks, we admit that we probably made an error in advising operation at this time. It is quite obvious however, that a fold offering so much chance for obstruction, particularly when edematous, would sooner or later be responsible for the development of a serious cholecystitis. As stated, slight thickening and mild inflammatory reaction were already present. The error made in this case would have been much greater if the initial obstruction had been caused by an acute inflammation in the absence of any anomalous obstructive lesion.

Recovery of the gall bladder from a diseased state when no shadow is obtained on cholecystogram, to a state when a normal shadow is revealed a few weeks later, was noted as early as 1927 by Lyon and Swalm (11). Since then it has been observed by numerous radiologists (Jenkinson (14) et al). The explanation is obvious. Any tissue can be temporarily diseased and lose its function and after subsidence of the inflammation return to a relatively normal status. We would naturally not expect the gall bladder to be an exception to this simple axiom. Unfortunately, a gall bladder would probably not stage many recoveries of this type, but after a few recurrent attacks would probably fail to show a shadow on the cholecystogram.

5. *Stone in the cystic duct.* As stated previously the lodgment of a stone in the cystic duct frequently produces complete obstruction, resulting in hydrops or empyema of the gall bladder, but much more frequently produces a partial obstruction or a complete one of short duration. Case 7, a woman 37 years of age, complaining of severe attacks of colicky pain of five months duration is a perfect example of partial obstruction of this type. At operation the gall bladder was not distended and appeared quite normal. The wall was bluish in color and not thickened. The gall bladder contained deeply colored bile and numerous small mulberry cholesterol stones. One was lodged in a cup-like fold of Heister (see Fig. 7) and was so completely surrounded by the fold that it appeared to be encysted. Cholecystogram revealed no shadow. Since the gall bladder appeared so normal, it seems safe to assume that the stone, though small, was encroaching on the lumen sufficiently to prevent the entry of enough bile to allow the development of a shadow on the cholecystogram.

6. *Tension induced by enlarged liver.* Several years ago Alexander and Bond (15) noted that cholecystograms performed on patients with enlarged livers usually revealed no shadow of the gall bladder in spite of the fact that at operation or post mortem examination there might be no evidence of cholecystitis or bile duct disease. The explanation of this would probably lie in two possibilities, first that the tension on the duct produced sufficient compression to prevent filling, or second, that the functions of the gall bladder itself were affected in some unknown manner secondary to the hepatic disease. The former explanation seems much more plausible.

7. *Compression or filling defect due to tumors or*

Fig. 7. Case 7. A stone is lodged in a Heister fold, and is encysted so completely that it could not be extracted without cutting the fold. Cholecystogram showed no shadow, even though the fundus of the gall bladder appeared normal. Several small stones were found in the gall bladder. It appears likely that the obstruction produced by the stone encysted in the cystic duct prevented the filling of the gall bladder.

enlarged lymph nodes. Tumors of the cystic duct itself are quite uncommon and are usually carcinomatous in type. Compression by enlarged lymph nodes is likewise uncommon but metastases from various sources may become implanted in the nodes about the cystic duct and produce partial or complete obstruction. Acute inflammation of the "sentinel" or cystic node might rarely obstruct the duct. Since the obstruction produced in the ways mentioned above are usually gradual, symptoms would be insidious. Severe pain of the type produced by stone in the duct or other comparatively sudden mechanisms will not be experienced.

8. *Obstruction due to anomalous hepatic or cystic artery.* Obstructions due to anomalous arteries are likewise uncommon and would likely be gradual in development.

SIGNIFICANCE OF DELAYED EMPTYING OF THE GALL BLADDER FOLLOWING THE FAT MEAL IN CHOLECYSTOGRAPHY

Previous to the present study, we were undecided as to the amount of diagnostic value that could be attributed to delayed emptying of the gall bladder following the fat meal during cholecystography. We are quite convinced now that at least on certain occasions much information can be gained from this delayed response of the gall bladder to the meal. Confirmation by examination of the gall bladder and cystic duct as removed at operation gives support to the supposition that delay in emptying may at least on some occasions be of definite diagnostic value. Normally there will be a sharp diminution in size of the cholecystographic shadow one hour after the fat meal. There may not be much decrease in density because the gall bladder has not had time to accumulate much bile and dilute its contents. Not infrequently the shadow has disappeared entirely.

Cases 1, 2 and 3 show a marked delay in emptying of the gall bladder following the fat meal. Each patient (see protocol of cases) complained of severe pain in the right upper quadrant with radiation posteriorly and other manifestations quite typical of gall bladder disease. Two of them had had a cholecystostomy previously, with relief for a time, but it is doubtful if this factor is of significance in interpretation of the findings. It seems obvious that the few adhesions

found at operation were secondary to the first operation, particularly in Case 1, and were not contributing to symptoms complained of before the time of the first operation. The recurrent symptoms in both cases (1 and 2) were identical to those complained of before the first operation. The etiological factors producing the symptoms at the time of the second operation were presumably present then before the first operation. The gall bladder shadow in the cholecystogram of all three patients was of normal density. In Case 1, who had had a cholecystostomy at another hospital one year previously, with relief for six months, there was an initial decrease in size of the gall bladder shadow but at the end of three hours following the fat meal it was still present and very dense (see Fig. 8). No further roentgenological observations were made. At operation a few filmy adhesions were found attached to the dome. The gall bladder wall was only very slightly thickened. The cystic duct was buried in adhesions and so stenosed that some degree of obstruction appears to have been present, particularly to the viscid bile which would be formed in the normally functioning gall bladder. Case 2 had a cholecystostomy, at another hospital, twelve years previously, with recurrence of typical gall bladder colic after a few years. Cholecystogram revealed a slightly deformed shadow of normal density. There was practically no evidence of emptying for 60 minutes after the fat meal. Unfortunately, through error no further roentgenograms were taken. At operation pericholecystitis with a thin walled gall bladder was found. The most significant finding was a small cystic duct buried in adhesions and so sharply angulated that obstruction to viscid bile would appear to be obvious. Case 3 was a woman aged 47, complaining of pain in the right upper quadrant of fifteen years' duration associated with a lot of vomiting. Cholecystogram revealed a gall bladder shadow of normal density which however failed to empty even five hours after the fat meal (see Fig. 4). Operation revealed a gall bladder of about normal appearance. On the strength of the manifestations so typical of gall bladder disease, and the failure of the gall bladder to empty following the fat meal, the organ was removed. There were practically no adhesions anywhere including the region of the cystic duct, but when the cystic duct was opened a very complicated maze of fibrous strands occupying a position consistent with folds of Heister was found (see Fig. 3). It was impossible to determine whether these strands were congenital or inflammatory in origin, but it was obvious that passage of bile through this maze would likely be impaired.

The fact that the gall bladder wall showed so little evidence of inflammation in the three cases described above, and that a definite lesion of obstructive character was found in the cystic duct along with failure of the gall bladder to empty following a fat meal has been interpreted as indicating that emptying was prevented by the lesion in the cystic duct. Although it is obvious that bile was able to enter the gall bladder an explanation of the inability to empty must be found. It is our opinion that the increased viscosity of the bile leaving the gall bladder was one of the most important mechanisms in the inability of the gall bladder to empty. Whether or not the position of the cystic duct in situ before removal at operation had any influence on the production of a valvular mechanism

Fig. 1. Microscopical section of the nodule projecting into the lumen as shown in Fig. 5. The lesion consists of connective tissue (C) in which a few muscle bundles (MI) are seen. It appears to be the residue of an ulcerative process, possibly associated with the gall stones. In proof of this assumption is the fact that the scar is densest at the mucosal side near the lumen.

bladder wall was diseased sufficiently to cast doubt as to the ability of the organ to concentrate, thereby making it difficult to tell whether the lack of shadow on the cholecystogram was caused by an obstruction of the cystic duct or by disease of the gall bladder wall.

Structures due to scar formation are undoubtedly common and probably account for the great majority of cases of hydrops or empyema of the gall bladder in which no stones are found.

Valve-like anomalies are probably congenital in origin and are quite frequent. Originally they were apparently large folds of Heister but became cup shaped because of the pressure exerted by viscid bile and concretions or stones from the gall bladder side. The fact that their concavity practically always faces the gall bladder suggests that they have acted as an obstruction to the contents of the gall bladder while being expelled through the duct. Case 5, a man aged 37, with pain of only three months duration, had a large well formed cup shaped valve-like fold at the junction of the cystic duct and neck of the gall bladder where the lumen was still 6 to 8 mm. in diameter. When filled this cup shaped fold, which extended all the way across the duct undoubtedly acted as a serious obstruction. Obviously, when collapsed, bile could enter the gall bladder without difficulty. If edematous it would obviously produce an obstruction in both di-

rections. Cholecystogram revealed no shadow, but it was performed a few days after an acute attack of right upper quadrant pain. Unfortunately, we did not get a later cholecystogram. Operation was not performed until several days later. On the assumption that his disease was of such short duration that recovery to a fairly normally functioning gall bladder may have taken place after the lapse of a few more weeks, we admit that we probably made an error in advising operation at this time. It is quite obvious however, that a fold offering so much chance for obstruction, particularly when edematous, would sooner or later be responsible for the development of a serious cholecystitis. As stated, slight thickening and mild inflammatory reaction were already present. The error made in this case would have been much greater if the initial obstruction had been caused by an acute inflammation in the absence of any anomalous obstructive lesion.

Recovery of the gall bladder from a diseased state when no shadow is obtained on cholecystogram, to a state when a normal shadow is revealed a few weeks later, was noted as early as 1927 by Lyon and Swalm (11). Since then it has been observed by numerous radiologists (Jenkinson (14) et al). The explanation is obvious. Any tissue can be temporarily diseased and lose its function and after subsidence of the inflammation return to a relatively normal status. We would naturally not expect the gall bladder to be an exception to this simple axiom. Unfortunately, a gall bladder would probably not stage many recoveries of this type, but after a few recurrent attacks would probably fail to show a shadow on the cholecystogram.

5. *Stone in the cystic duct.* As stated previously the lodgment of a stone in the cystic duct frequently produces complete obstruction, resulting in hydrops or empyema of the gall bladder, but much more frequently produces a partial obstruction or a complete one of short duration. Case 7, a woman 37 years of age, complaining of severe attacks of colicky pain of five months duration is a perfect example of partial obstruction of this type. At operation the gall bladder was not distended and appeared quite normal. The wall was bluish in color and not thickened. The gall bladder contained deeply colored bile and numerous small mulberry cholesterol stones. One was lodged in a cup-like fold of Heister (see Fig. 7) and was so completely surrounded by the fold that it appeared to be encysted. Cholecystogram revealed no shadow. Since the gall bladder appeared so normal, it seems safe to assume that the stone, though small, was encroaching on the lumen sufficiently to prevent the entry of enough bile to allow the development of a shadow on the cholecystogram.

6. *Tension induced by enlarged liver.* Several years ago Alexander and Bond (15) noted that cholecystograms performed on patients with enlarged livers usually revealed no shadow of the gall bladder in spite of the fact that at operation or post mortem examination there might be no evidence of cholecystitis or bile duct disease. The explanation of this would probably lie in two possibilities, first that the tension on the duct produced sufficient compression to prevent filling, or second, that the functions of the gall bladder itself were affected in some unknown manner secondary to the hepatic disease. The former explanation seems much more plausible.

7. *Compression or filling defect due to tumors or*

Fig. 7. Case 7. A stone is lodged in a Heister fold, and is encysted so completely that it could not be extracted without cutting the fold. Cholecystogram showed no shadow, even though the fundus of the gall bladder appeared normal. Several small stones were found in the gall bladder. It appears likely that the obstruction produced by the stone encysted in the cystic duct prevented the filling of the gall bladder.

enlarged lymph nodes. Tumors of the cystic duct itself are quite uncommon and are usually carcinomatous in type. Compression by enlarged lymph nodes is likewise uncommon but metastases from various sources may become implanted in the nodes about the cystic duct and produce partial or complete obstruction. Acute inflammation of the "sentinel" or cystic node might rarely obstruct the duct. Since the obstruction produced in the ways mentioned above are usually gradual, symptoms would be insidious. Severe pain of the type produced by stone in the duct or other comparatively sudden mechanisms will not be experienced.

8. *Obstruction due to anomalous hepatic or cystic artery.* Obstructions due to anomalous arteries are likewise uncommon and would likely be gradual in development.

SIGNIFICANCE OF DELAYED EMPTYING OF THE GALL BLADDER FOLLOWING THE FAT MEAL IN CHOLECYSTOGRAPHY

Previous to the present study, we were undecided as to the amount of diagnostic value that could be attributed to delayed emptying of the gall bladder following the fat meal during cholecystography. We are quite convinced now that at least on certain occasions much information can be gained from this delayed response of the gall bladder to the meal. Confirmation by examination of the gall bladder and cystic duct as removed at operation gives support to the supposition that delay in emptying may at least on some occasions be of definite diagnostic value. Normally there will be a sharp diminution in size of the cholecystographic shadow one hour after the fat meal. There may not be much decrease in density because the gall bladder has not had time to accumulate much bile and dilute its contents. Not infrequently the shadow has disappeared entirely.

Cases 1, 2 and 3 show a marked delay in emptying of the gall bladder following the fat meal. Each patient (see protocol of cases) complained of severe pain in the right upper quadrant with radiation posteriorly and other manifestations quite typical of gall bladder disease. Two of them had had a cholecystostomy previously, with relief for a time, but it is doubtful if this factor is of significance in interpretation of the findings. It seems obvious that the few adhesions

found at operation were secondary to the first operation, particularly in Case 1, and were not contributing to symptoms complained of before the time of the first operation. The recurrent symptoms in both cases (1 and 2) were identical to those complained of before the first operation. The etiological factors producing the symptoms at the time of the second operation were presumably present then before the first operation. The gall bladder shadow in the cholecystogram of all three patients was of normal density. In Case 1, who had had a cholecystostomy at another hospital one year previously, with relief for six months, there was an initial decrease in size of the gall bladder shadow but at the end of three hours following the fat meal it was still present and very dense (see Fig. 8). No further roentgenological observations were made. At operation a few filmy adhesions were found attached to the dome. The gall bladder wall was only very slightly thickened. The cystic duct was buried in adhesions and so stenosed that some degree of obstruction appears to have been present, particularly to the viscid bile which would be formed in the normally functioning gall bladder. Case 2 had a cholecystostomy, at another hospital, twelve years previously, with recurrence of typical gall bladder colic after a few years. Cholecystogram revealed a slightly deformed shadow of normal density. There was practically no evidence of emptying for 60 minutes after the fat meal. Unfortunately, through error no further roentgenograms were taken. At operation pericholecystitis with a thin walled gall bladder was found. The most significant finding was a small cystic duct buried in adhesions and so sharply angulated that obstruction to viscid bile would appear to be obvious. Case 3 was a woman aged 47, complaining of pain in the right upper quadrant of fifteen years' duration associated with a lot of vomiting. Cholecystogram revealed a gall bladder shadow of normal density which however failed to empty even five hours after the fat meal (see Fig. 4). Operation revealed a gall bladder of about normal appearance. On the strength of the manifestations so typical of gall bladder disease, and the failure of the gall bladder to empty following the fat meal, the organ was removed. There were practically no adhesions anywhere including the region of the cystic duct, but when the cystic duct was opened a very complicated maze of fibrous strands occupying a position consistent with folds of Heister was found (see Fig. 3). It was impossible to determine whether these strands were congenital or inflammatory in origin, but it was obvious that passage of bile through this maze would likely be impaired.

The fact that the gall bladder wall showed so little evidence of inflammation in the three cases described above, and that a definite lesion of obstructive character was found in the cystic duct along with failure of the gall bladder to empty following a fat meal has been interpreted as indicating that emptying was prevented by the lesion in the cystic duct. Although it is obvious that bile was able to enter the gall bladder an explanation of the inability to empty must be found. It is our opinion that the increased viscosity of the bile leaving the gall bladder was one of the most important mechanisms in the inability of the gall bladder to empty. Whether or not the position of the cystic duct in situ before removal at operation had any influence on the production of a valvular mechanism

Fig. 8. Response of the cholecystographic shadow to the fat meal in Case 1. Note that there was an initial decrease in size of the shadow but at the end of 3 hours a dense shadow is still seen. The gall bladder wall was only slightly diseased, but the cystic duct was stenosed and buried in dense adhesions. It appears that the dense fibrous tissue and the coincidental stenosis acted as an obstruction perhaps explaining the patient's symptoms and the failure of the gall bladder to contract normally after the fat meal.

cannot be determined. The cystic duct is so small that the occasional presence of a valvular action produced by anatomical lesions and adhesions does not appear hopelessly fantastical. The symptoms of these patients were very similar to those complained of by patients who have stones lodged or encysted in the cystic duct (e.g. Case 7). This fact again brings up the question as to whether the pain is produced by the presence of the stone in the gall bladder or by the gall bladder's futile efforts to empty itself when stimulated to do so. It is naturally difficult to determine this since in a given case of stone in the cystic duct, both mechanisms exist.

All these patients were relieved of their pain. Case 3 gained fifty pounds, however, and is now complaining of pain in the lumbosacral region and in the cardiac region, but none in the right upper quadrant where pain was very severe on entrance.

The three cases showing failure of the gall bladder to empty following the fat meal do not represent all the cases of that type observed during this study, but represent the ones showing obvious obstructive lesions. Others have been observed but no lesions of an obstructive character in the cystic duct were found. In one case the shadow was deformed as if the gall bladder were folded upon itself. At operation a dense band of adhesions was found extending from the liver across the gall bladder and attached to the duodenum. The fundus was therefore fixed, and any muscular activity on the part of the gall bladder would appear to be restricted or eliminated entirely.

SUMMARY

While examining the gall bladders from routine cholecystectomies during the past year or two several instances of partial obstruction of the cystic duct were encountered. A classification of the various types of lesions which are apt to produce partial obstruction has been discussed. Important lesions in this group are adhesions, kinks, an acute inflammatory process, anomalous folds of Heister, stone in the cystic duct and compression by extrinsic factors. Complete obstruction such as illustrated by hydrops and empyema is not discussed because the mechanisms of production and pathology are so clearly understood. It is obviously very difficult to prove that a given lesion of the cystic duct is producing an incomplete obstruction, but an analysis of the cases studied has led us to believe that on many occasions the lesion in the cystic duct represents perhaps the only significant lesion of the gall bladder and that on other occasions it may be the instigating factor of disease in the gall bladder. It is difficult to demonstrate the obstruction experimentally, not only because a criteria of the degree of obstruction based on the rapidity of flow of bile of a given viscosity through the cystic duct would be difficult to establish, but also because of the fact that accurate reading could only be obtained after cholecystectomy. Removal of the gall bladder would of necessity destroy the attachment of the cystic duct thereby altering the factors producing the obstruction, because fixation and adhesions are bound to be important factors in a great majority of the obstructions even though the primary lesion may be a congenital anomaly involving the folds of Heister.

It should be emphasized that in a great majority of instances, an anatomical lesion may be present without exerting any obstructive influence until an acute

inflammatory process is implanted upon it. There is very good evidence that acute inflammation of the cystic duct occurs commonly. The fact that adhesions about the cystic duct are so commonly encountered in gall bladder disease is in itself fairly good proof. The presence of severe clinical manifestations typical of gall bladder disease, with a demonstrable lesion of the duct in the absence of significant pathologic changes in the gall bladder wall, as was the case in most of the patients studied in this series, is also suggestive proof that the lesion in the cystic duct may be an important factor in the production of the manifestations. This is particularly true if cholecystectomy relieves the patient's symptoms.

A consideration of some of the patients in this series suggests very decisively that at least in some instances the failure of the gall bladder to empty (as determined by cholecystographic study) following the fat meal is indicative of serious cholecystic disease. It is conceivable that the failure of emptying might be due to (1) obstructive lesions of the cystic duct; (2) inefficient muscular response on the part of the gall bladder (e.g. atony) or (3) spasm of the sphincter of Oddi. In this study, however, attention was directed only to mechanisms involved in the first group.

DISCUSSION

DR. B. B. VINCENT LYON (Philadelphia, Pa.): I consider the paper of Drs. Cole and Rossiter a most interesting one and a most timely one. I feel that they have made an important contribution that sheds new light and gives a probable explanation as to why occasional patients who have suffered severe pain, considered to be gall bladder in origin, make clinical satisfactory recoveries after the removal of an innocent-looking gall bladder. Their studies have pointed out that the lesion lies in the cystic duct and not in the gall bladder. I wish Dr. Cole would later on publish a follow-up of these cases now reported, in regard to their complete clinical improvement.

Their studies also suggest the importance of bearing in mind the likelihood of some form of cystic duct obstruction in all patients who showed delayed or deficient emptying

to cholecystographic study. We should also bear in mind that this delay in emptying is equally observable on biliary drainage.

The normal gall bladder, in my experience, will empty nearly completely on single, or sometimes, multiple stimulations with magnesium sulphate or peptone, or a combination of the two, without having recourse to fatty stimulants such as olive oil or oleic acid. When a gall bladder will respond only to the latter, although physiologically this is believed to be the best stimulant, I consider such a gall bladder to be abnormal to a certain degree.

This sounds paradoxical since it does not check with the emptying response to the fat-full meal during cholecystography, except for the fact that in both there is evidence of delayed or inefficient emptying. But the fault may lie in some lesion producing partial obstruction of the cystic duct rather than lack of proper tonicity of the gall bladder wall.

In 1927, Dr. Swalm and I reported our observations regarding the frequency of partial or temporarily complete obstruction of the cystic duct produced by catarrh or edema, and demonstrated how it can be recognized. We are constantly picking up additional cases in our clinic and practice each year. It is gratifying to report that the majority of these patients have become symptomatically well, with return to normal cholecystograms.

Followed up carefully over a number of years, most patients in this group have not yet developed a surgical form of cholecystitis or of cystic duct obstruction, however, a small minority of these cases who have failed to return to normal cholecystographic response have usually proved at operation to be cases of cholesterosis. It is possible that some of the abnormalities that Cole and Rossiter have described may also be associated with catarrhal obstruction or edema, and it would be most important if we could learn how to segregate this necessarily surgical group, and urge that they be operated upon.

I noted that two of their seven cases (28.5 per cent) have had previous cholecystostomies. This brings up a question as to how frequently this operation achieves complete recovery and how frequently it is followed by relapse. Excepting cholecystostomies for empyema or for acute suppurative cholecystitis, where the operative risk of cholecystectomy is high, I have frequently expressed the opinion that cases submitted to surgery should have sufficient pathology found on operating table to warrant surgical removal rather than surgical drainage of the gall bladder. Such successful results as accrue to surgical drainage of a gall bladder without cystic duct obstruction can be achieved with greater safety by non-surgical biliary drainage.

Also it has been noted by many of us that some surgeons, usually the less skillful, have assumed that cholecystostomy is preferable to cholecystectomy on the ground that if anything should "go wrong", a cholecystectomy or an anastomotic operation between gall bladder and stomach or duodenum may still be done. In the latter case, I believe that the surgeon must make very sure indeed that the cystic duct is not obstructed by any of the conditions Drs. Cole

and Rossiter have pointed out. Otherwise such an operation is a useless procedure with regard to the welfare of the patient.

Again, I congratulate the authors on the worthwhileness of this paper.

DR. ALBERT F. R. ANDRESEN (Brooklyn, N. Y.): It has been very interesting and important to have our attention called to these anatomical conditions causing difficulty in gall bladder emptying. However, one factor which may cause interference both with filling and emptying of the gall bladder has not been brought out. If there has not been sufficiently frequent and forceful stimulation to gall bladder evacuation, its wall may become atonic and its contents too concentrated, the latter interfering with filling, and both with emptying. Persons priding themselves on eating only once a day or who because of digestive symptoms have cut down on quantity and frequency of meals, thereby causing insufficient natural stimulation to the emptying of the gall bladder, will therefore usually show either no gall bladder shadow, or a faint shadow, after dye administration, or if a gall bladder shadow is seen it may show little or no decrease in size after the fatty meal. In such cases it is our custom to prescribe a well balanced diet, with sufficient fat for proper gall bladder stimulation and with an adequate vitamin and mineral content, meanwhile attending to the patient's general condition, removal of focal infections and hygienic measures. After four to six weeks we have another gall bladder series, when in many cases the findings may be normal or there may be found definite evidences of disease, such as stones, deformities or a persistent failure to fill, indicating, possibly, the need for operation.

DR. JOHN R. TWISS (New York, N. Y.): I should like very much to express my appreciation of this very instructive paper and also the privilege of hearing Dr. Lyon and Dr. Andresen discuss it, and to add further a few points from a viewpoint of practical experience.

We have followed Dr. Lyon's method of study in gall bladder disease at the New York Post-Graduate Hospital for a number of years and have studied approximately four thousand patients, doing both X-ray examinations and duodenal drainage on all of them. We have found, as Dr. Andresen has, that in many patients there will be no visualization of the gall bladder on initial examination and with biliary tract drainage no concentrated gall bladder bile obtained. In many cases where gall bladder bile is obtained, it will be only after olive oil and not after magnesium sulphate stimulation, as stated by Dr. Lyon.

I should like to emphasize what Dr. Andresen says, that a trial course of medical treatment is in all cases indicated, especially following repeated duodenal drainage. In many cases these patients will later show normal visualization and be entirely relieved of their symptoms. We feel that operation is indicated only if after a period of trial medical treatment, the patient's symptoms persist and there is persistently no visualization of the gall bladder, and no concentrated gall bladder bile obtained on drainage.

The Endocrines in Relation to the Gastro-Intestinal Tract*

By

J. B. COLLIP, M.D.

MONTREAL, CANADA

I THINK that it is peculiarly fitting that gastroenterologists are interested in endocrinology, since it may be truly said that modern endocrinology, so much dependent as it is upon the isolation of active principles from endocrine glands and tissues, originated in the gastro-intestinal field. I refer, of course, to the epoch-making discovery of duodenal hormone secretin by Bayliss and Starling in 1902 (1). Sir Frederick Gowland Hopkins was present on this memorable occasion, and in a recent writing (2) he recalls the incident as follows: "It was my privilege to be present at University College, London, on the very day (Jan. 16, 1902) when Bayliss and Starling first made the *experimentum crucis* which definitely established the existence and functions of secretin as a chemical entity. I saw with them for the first time a copious secretion flow from the duct of a completely denervated pancreas of a dog as the result of injecting intravenously an extract from the intestinal epithelium. I remember too the day, a little later, when a discussion at Gonville and Caius College, Cambridge, led Starling to select the name Hormone for secretin and substances with analogous functions.

Bayliss and Starling used dilute hydrochloric acid to prepare their extract of the duodenal mucosa, but since they were able to show that intravenous injection of the acid alone had no secretagogue action they concluded that the positive effect of their extract was due to an active principle obtained from the duodenal tissue. They showed also that the introduction of acid into the duodenum produced a copious secretion of pancreatic juice even though the intestinal segment had previously been denervated.

Ivy and co-workers (3) transplanted a loop of intestine and the tail of the pancreas under the skin, thus severing their nerve connections, and found that the introduction of acid into the isolated duodenum produced a secretion from the pancreatic transplant. Since the intravenous injection of acid alone proved ineffective, these experiments gave conclusive proof of the hormonal mechanism of activation of the pancreatic acinar cells. Mellanby and Huggett (4) demonstrated that secretin exists preformed in the mucosa, from which it can be extracted by water, alcohol and other solvents, as well as by dilute acid.

In view of the primitive nature of the gastro-intestinal tract and the glandular appendages derived therefrom, it is to be expected that many hormonal mechanisms of an essentially local character would be developed. For the same reason it could be predicted that the digestive tract would be less under the control of those endocrine glands which embryologically have a different origin than are other organs and tissues of mesoblastic or ectodermal origin. There are definite functional interrelationships between various glands such as the pituitary, the parathyroids and the suprarenals, and the gastro-intestinal tract, but these I

think, are of more recent development than is, for instance, the control of the thyroid, the suprarenal cortex and the gonad by the anterior pituitary.

Since the discovery of secretin by Bayliss and Starling, much experimental evidence has been published showing the existence in and extraction from parts of the alimentary tract of other hormones or hormone-like substances. Thus Edkins in 1906 (5, 6) and Edkins and Tweedy in 1909 (7) found that a hydrochloric acid extract of the pyloric mucosa had a powerful secretory effect upon the gastric glands when injected intravenously. They attributed this effect to the presence of a special hormone "gastrin" which they thought is liberated into the blood stream during digestion.

Later work by Koch, Luckhardt and Keeton (8), in which it was shown that extracts of other tissues have a gastric secretagogue action, deprived the work of Edkins of much of its physiological significance. It was shown by Popielski (9, 10) that histamine is a powerful stimulant of gastric secretion, and the "gastrin" effect was attributed thereafter by many to histamine. Ivy and Farrell (11, 12) and Kim and Ivy (13) were able to demonstrate that there is a secretagogue substance actually present in the blood during digestion. Very recently Komarov (14), working in Babkin's laboratory, has obtained an extract of pyloric mucosa by the use of trichloroacetic acid which is said to be free of histamine, choline and other organic crystalloids, and which is a powerful secretagogue. If this work is subsequently confirmed, it would appear to establish on a definite and firm basis the original "gastrin" theory of Edkins.

Ivy and Oldberg (15) have extracted from the duodenum a substance which causes contractions of the gall bladder. They have been able to remove histamine and other vaso-dilator substances from their extracts and still retain the specific physiological activity. They have named the substance "cholecystokinin".

Another intestinal hormone termed "enterogastrone" has been extracted from intestinal mucosa by Gray, Bradley and Ivy (16). This substance has the property of inhibiting the hunger contractions of the dog's stomach, and the secretory effect of injected histamine.

Ludany and co-workers (17, 18, 19, 20) claim to have extracted from the mucosa of the stomach and small intestine a principle which stimulates the movements of the intestinal villa and the name "villikin" has been suggested for this substance. The introduction of hydrochloric acid into the duodenum is said to increase the production of villikin and at the same time the absorption of glucose is facilitated (21). In isolated loops of jejunum villikin administration likewise increased the rate of glucose absorption (22). The authors suggested that this hormone is present in the intestinal mucosa in the form of a prohormone

*From the Department of Biochemistry, McGill University, Montreal.

which can be activated by hydrochloric acid since they were able to extract an inactive precursor by other means (23).

In a recent communication, Nasset, Schriffrin and Belasco (24) extending the earlier work of Nasset, Pierce and Murlin (25) and of Nasset (26), appear to have established that an intestinal secretory hormone "enterocrinin," distinct from secretin, can be extracted from both the small and large intestine of dogs and pigs. Enterocrinin acts upon the intestinal glands, causing an increase both in volume and in enzyme content of the succus entericus. Acid in the intestine is not the stimulus for the liberation of enterocrinin as it is for secretin, since hydrochloric acid introduced directly into the duodenum in acute experiments did not excite the glands of isolated segments of jejunum to secrete intestinal juice. It caused a marked increase in the oxygen consumption of isolated dog intestinal mucosa. This work of Nasset and coworkers on the isolation of an intestinal secretagogue fits in well with the demonstration by Florey and Harding (27) that the glands of Brunner are under hormonal control. These authors observed an active secretory process after the ingestion of food in the transplanted duodenum, all nerve connections to which had been severed.

All of the hormonal mechanisms thus far mentioned have been more or less local and circumscribed. It should be mentioned in passing that the haemopoietic substances found in the stomach and liver may be considered as belonging to the hormone group. These substances presumably have a zone of activity outside of the gastro-intestinal tract.

Extracts have been prepared from intestine by various methods, and by different workers, which have the property of producing hypoglycemia (28-38). It is possible that further work along these lines will in the future establish some important connection between the intestinal mucosa and some phases of carbohydrate metabolism, more especially those relating to clinical diabetes.

Recently Hallier (39) has published an extensive study of the basal granulated (also known as the argentaffin) cells of the intestine in the guinea pig and rabbit. He claims that prolonged treatment with thyroid hormone or posterior pituitary extract decreases their number while insulin has no effect upon them. In this connection attention should be called to the fact that the argentaffin granules in the intestine have frequently been regarded as identical with adrenalin, and Feyrter and Unna (40) were able to extract a pressor principle from an argentaffin carcinoid tumour of the appendix. The action of this extract could be reversed by ergotoxin just as that of adrenalin can be reversed.

Petri (41) made the observation that removal of the stomach and the first part of the duodenum causes the appearance of pellagra-like symptoms in young dogs. It is interesting that oral administration of large quantities of the vitamin B₂-complex did not cure this condition, although it makes its course somewhat milder. The author compares these findings with the ineffectiveness of vitamin B₂ treatment in some acute cases of pellagra in man and thinks that the condition is due to an inability of the organism to utilize orally administered vitamin B₂ in the absence of the stomach and duodenum.

It is probably safe to assume that the normal func-

tioning of the gastro-intestinal tract in the intact individual is associated with the continuous action of a number of hormones arising from various endocrine glands. It is difficult to single out very many specific effects of hormones upon the gastro-intestinal tract. The maintenance of normal water and salt content of the tissue must be of prime importance, and here as elsewhere the suprarenal cortex and the parathyroid glands no doubt have much to do with regulation of these factors.

The whole neuromuscular mechanism of the gastro-intestinal tract is responsive to adrenalin and acetylcholine, and glandular activity is modified by these same active principles.

That pituitary hormones are not essential for the functioning of the gastro-intestinal tract is shown by the failure of hypophysectomy to produce any well-defined changes in the digestive functions. Splanchnomegaly has been produced in dogs by the administration of anterior lobe extracts and in the pigeon Riddle and co-workers have shown that prolactin causes a considerable degree of enlargement of the liver. More recently Bates, Riddle, Lahr and Schooley (42), in an extension of this latter study, found that prolactin may also produce a relative over-growth of the intestines both in the normal and hypophysectomized pigeon. Prolactin did not produce splanchnomegaly in the rat, but Best and Campbell (43), using other anterior lobe preparations, obtained marked enlargement of the liver with fatty infiltration in this species.

While referring to the anterior lobe mammary secretagogue prolactin, it is of interest to note that the crop gland of the pigeon, although part of the alimentary tract, may be regarded as the equivalent in this form of the mammary gland of the mammal. Riddle (44) discovered that the crop gland can be stimulated to enlarge and produce crop milk, and has made use of this response in the immature dove or pigeon to assay and standardize prolactin. Later Lyons and Page (45, 46) showed that this test can be made much more sensitive if the extract to be tested is injected intradermally over the crop sac area.

In 1910, Franchini (47) found that pituitary extracts, especially those of the posterior lobe, caused ulcerations in the gastric and intestinal mucosa of the guinea pig and rabbit. More recently, Dodds and his co-workers (48) made similar observations and considered the possibility that this action of posterior lobe extracts may be due to a special "gastrotoxic factor." Hanke (49) produced similar changes using adrenalin or insulin, and these findings have been confirmed by Selye, Stehle and Collip (50) who showed, furthermore, that adrenalectomy or partial hepatectomy sensitizes the rat considerably to this action of adrenalin, pituitrin or insulin. The latter authors, using purified preparations of the oxytocic, melanophore and vasopressor principle showed, furthermore, that in pituitary extracts it is the latter hormone which is responsible for the production of these ulcers. Since it has been proven that not only hormones but various other damaging agents cause similar gastric ulcers (Selye (51)) further experiments would have to be performed before one could regard the findings of Dodds as a significant proof of the existence of a specific interrelationship between the posterior lobe and the gastric mucosa. In this connection, one might also mention that posterior lobe extracts may inhibit the gastric secretion otherwise produced by histamine

(Dodds, et al 52, 53)). In fact an inhibitory action of these extracts on the secretion of the stomach was observed as early as 1916 by Pal (54). Gastric motility is increased following administration of posterior lobe extracts in man (Zanasi (55)).

In conclusion I would call to your attention the peculiar effect of the thyroid hormone upon calcium metabolism. Exhibition of this hormone may cause a great increase in the elimination of calcium salts. The increased excretion of these is almost entirely by bowel. This is in sharp contrast to the effect of the parathyroid hormone which causes a great increase in calcium excretion, but here nearly all of the excretion is by way of the kidney.

DISCUSSION

DR. ANDREW C. IVY (Chicago, Ill.): Mr. President, Ladies and Gentlemen: This excellent review does not call

for much discussion. There is really nothing to add. However, I should like to have heard Dr. Collip spend a little more time on the hormone called duodenin.

I have followed the literature on that phase of the gastro-intestinal hormones very closely, but have done no work on duodenin. I do not think that the crucial experiment, showing that duodenin actually exists, has yet been performed. I should like to ask Dr. Collip to say a little more about duodenin.

DR. VICTOR C. MYERS (Cleveland, Ohio): I doubt if I am competent to make many comments on Dr. Collip's excellent review. Of course, we are all aware of Dr. Collip's standing in the field of endocrinology, although from conversation I have just had with him, I doubt if in recent years his interest has been particularly in our field of gastro-enterology.

As you know, it was Dr. Collip whom Dr. Macleod called upon to make the first clinical preparations of insulin, and it was Dr. Collip who early made an active extract of the parathyroid gland. His opinions regarding this whole field are authoritative opinions even though in this presentation most of his statements may have been taken from the literature.

DR. WALTER G. KARR (Philadelphia, Pa.): I really haven't anything to add to this excellent presentation and review of Dr. Collip's. Certainly gastro-enterologists should realize the great advances that have been made since the time that we considered the stomach a dumping and mixing bag and the intestine a mere channel for digestion and absorption. The relation of the autonomic nervous system and various hormones to problems of absorption is of especial interest. Dr. Collip didn't mention some work which I have been slightly interested in; the relation of the adrenal gland to absorption from the gastro-intestinal tract, and I wonder what he thinks of the work of Verzar and associates, and how important he considers it to be.

DR. THOMAS R. BROWN (Baltimore, Md.): I should like to ask a question. Dr. Collip's paper brought back the days when I was working with Starling and Bayliss at the University and saw some of the preparations. I should like him to speak a little bit about the increased and diminished activity in certain of these endocrine glands, thyroid, both as to the secretory and absorptive phases.

DR. BORIS P. BABKIN (Montreal, P. Q., Canada): It was a great pleasure to listen to Dr. Collip's presentation and to learn that he is interested in the effect of different hormones on the gastro-intestinal tract. There is no doubt that with his ability and mastery he could add very much to our knowledge about the relations between the endocrine glands and the alimentary canal.

He said very modestly that the effect of the endocrine glands on the gastro-intestinal tract is not very great. That is not quite so, I think. There are indications that in many respects the functions of the gastro-intestinal tract are influenced by the endocrine glands. Consider, for instance, the effect of the parathyroid glands on the gastric secretion. In such case the nervous phase of the gastric secretion is diminished, whereas the chemical phase is increased, which results in a hypersecretion. Therefore it is quite possible that the hypofunction of the parathyroid glands may play a certain part in the hypersecretory state of the stomach. I am convinced that it is a very promising field, and, if Dr. Collip will be interested in the application of his knowledge to the problem of that kind, gastro-enterology will gain greatly.

DR. JAMES B. COLLIP (Montreal, Canada, closing the discussion): Mr. Chairman, I wish to thank the various discussers for their remarks.

As Dr. Ivy may suspect, I deliberately avoided entering upon any detailed discussion on this vexing question about duodenin; however, for those who wish, I have included

ten references in the paper. I am very much puzzled over this whole thing. You all know that in the early days, I think about 1925, Dr. Ivy and his coworkers obtained a definite insulin reaction from some extracts which they prepared from duodenal mucosa. I am not certain whether they got results from gastric mucosa. So it can be said that there is very definite evidence in the literature that insulin or an insulin-like substance may be extracted from intestinal mucosa.

There have been a number of capable people working on this question of extracts of duodenum which supposedly influence carbohydrate metabolism. I am thinking particularly of Dr. LaBarre and his coworkers, and one wonders, when LaBarre has published such clear-cut results, why there has not been confirmation after all these months, and even years. If LaBarre's work is ever confirmed, I would be inclined to be much more convinced that there is such a substance.

I am sorry that I cannot answer Dr. Karr's question about the influence or the possible effect of the suprarenal upon the gastro-intestinal tract. Personally, I do not think that it is fair to consider what happens in an animal in

which the suprarenals are completely removed, or what happens in an animal which one renders practically moribund by giving excess doses of parathyroid hormone. In both of these cases, as has been shown in the case of the dog, renal insufficiency develops, and I myself showed in connection with the parathyroid hormone that one may get profound changes, seen both by gross and microscopic examination, in the mucosa—chiefly in the stomach.

I also deliberately refrained from saying much about the effect of the different endocrines on the gastro-intestinal tract because I do not think that we know very much about it. I am delighted to tell you that Dr. Babkin tells me that he is going to undertake—with his own special methods and with his own special skill—a study of the various hormones upon the gastric, pancreatic and intestinal secretion. I will be very happy indeed to collaborate with him in that study if he so desires.

I feel, as he says, that there is a lot to be found out, but until we have this information, perhaps the less said the better. I know practically nothing from personal experience about the effect of thyroid upon gastric secretion.

Treatment of the Hemorrhagic Tendency in Jaundice; with Special Reference to Vitamin K*

By

ALBERT M. SNELL, M.D.,† HUGH R. BUTT, M.D.‡

and

ARNOLD E. OSTERBERG, Ph.D.‡

ROCHESTER, MINNESOTA

THE hemorrhagic diathesis associated with obstructive jaundice has long been a serious cause of mortality and a great handicap to successful surgical treatment. There have been no adequate methods which would foretell the tendency to bleed in such cases and attempts at treatment have been far from satisfactory. Theories in regard to the coagulation defect have been numerous but most of them have been insufficiently supported by objective evidence. It has been shown repeatedly that the hemorrhagic state could not be attributed to a deficiency in calcium, fibrinogen, blood platelets or thromboplastin, and it seems equally certain that the presence of any regurgitated elements of bile in the blood stream was not the causative factor. The conception that hemorrhage might be due to a deficiency of some substance normally absorbed from the intestine and necessary for the coagulation of blood is of recent origin and begins with pioneer work of Dam, which will be considered in a substance necessary for coagulation was lacking, dates concerned, the first evidence which showed that any substance necessary for coagulation was lacking dates from the studies of Quick and his associates, who presented evidence which indicates that in jaundice there is a diminished quantity of prothrombin in the circulating blood and that the deficiency in this substance is responsible for the disturbance of the process of coagulation.

Prothrombin is a component of the plasma pro-

teins known physiologically by its capacity to form thrombin; aside from this fact and its constant association with plasma globulin, little is known of its chemical or physical properties. Perhaps it is best, as suggested by Patek and Taylor (1937), to regard prothrombin as a physiologic complex rather than as a single chemical substance. Although methods for measuring the prothrombin content of plasma have been little used, within the past few years several conditions have been reported in which there apparently is a diminution in the concentration of prothrombin in the plasma. Such a deficiency occurs in chicks fed on diets lacking in certain fat-soluble substances, in experimental animals with external or renal biliary fistulas, in dogs whose livers have been injured by chloroform and in cattle fed on toxic sweet clover hay. All of these conditions are associated with a well marked hemorrhagic tendency. It is interesting to note that in each of these examples of prothrombin deficiency there is either an exclusion of bile from the bowel, injury of the liver by toxic substances, or a state of nutritional deficiency. There is now good evidence to indicate that the factors common to these forms of the hemorrhagic diathesis have been found.

Between 1929 and 1935, several investigators reported a bleeding tendency among chicks reared on artificial diets but it was not until 1935 that Henrik Dam (8) reported that the deficiency factor responsible for the hemorrhage in these animals was a fat-soluble substance which he designated as "vitamin K" (coagulations vitamin). The bleeding tendency in these chicks was found to be associated with a de-

crease in the concentration of prothrombin in the plasma and on administration of the nonsaponifiable portion of the fat of the hog liver, alfalfa or other substances that contain the hypothetical vitamin, the bleeding ceased and the concentration of prothrombin rose to normal limits. Time does not permit a retelling of the interesting history of the development of knowledge of Vitamin K; for this and other details, the bibliography of previous articles should be consulted (4, 6, 14, 16, 21). It suffices to say here that Vitamin K apparently is widely distributed in nature; the materials which are known to contain the vitamin, as well as those which have been found to have no protective effect, are mentioned in Table I. Although little is known of its exact chemical and physical properties, it has been prepared in rather concentrated form and has been recently crystallized by Almquist (1937) (2, 3).

The probable relation of a deficiency of vitamin K to deficiency of prothrombin in the plasma of dogs or human beings with biliary fistula or in cases of obstructive jaundice is reasonably clear, since bile acids are required for the normal absorption of fat soluble substances from the bowel and since in the conditions mentioned bile is usually completely excluded. Two factors, the presence of bile in the bowel and a hypothetical fat-soluble vitamin, are therefore known to be of importance in maintaining a normal concentration of prothrombin.

A third and equally important factor remains to be considered, namely, the rôle of the liver in prothrom-

bin deficiency. As will be pointed out, there is both experimental and clinical evidence to show that the liver is intimately concerned in the fabrication, storage or activation of prothrombin, but by just what mechanism this is accomplished is not yet known. Fatal bleeding associated with a low concentration of prothrombin is not uncommon in chronic atrophy (cirrhosis) of the liver, even if the affected person is not deeply jaundiced, and in spite of the presence of bile in the intestine. Chloroform intoxication in animals produced, as Smith and his coworkers have shown, a marked deficiency of prothrombin and a resulting hemorrhagic diathesis. Necrosis of the liver was also demonstrated by Roderick in animals that were dying of the toxic hemorrhagic disease caused by sweet clover hay. Finally, there is some clinical evidence which indicates that in the presence of severe hepatic injury, prothrombin is formed poorly even if Vitamin K and bile salts are administered.

METHODS FOR DETERMINING THE CONCENTRATION OF PROTHROMBIN

Since a large part of the consideration to follow is based upon the results of determinations of the concentration of prothrombin, it is necessary to describe the methods briefly and consider their theoretical basis and adaptability to general use. Such methods are hampered in their application chiefly because of the lack of adequate chemical and physical data on the prothrombin complex itself. Quick and his associates have devised an indirect method which depends on the clotting time of recalcified plasma to which thrombo-

Fig. 2. The effect of Vitamin K and bile on prothrombin clotting time and the concentration of prothrombin in the plasma in a case of obstructive jaundice.

plastin has been added. Since many investigators (18) have shown that fibrinogen is not lacking in jaundiced patients, Quick's method leaves prothrombin as the only variable. The test is simple and gives clinically consistent results which closely parallel those obtained with Nygaard's coagulation index. We have not observed an abnormal tendency to bleed in any jaundiced patient with a normal prothrombin time (twenty seconds); whereas free bleeding may ensue with prothrombin times of from forty-five to one hundred seconds, or higher. In cases in which the prothrombin time is prolonged, surgical or other trauma may initiate bleeding, or it may occur spontaneously. Unfortunately, Quick's method may give normal values even when the concentration of prothrombin is reduced to a dangerously low level. For this reason Quick has suggested that the performance of the test upon serial dilutions of the plasma in question will give an approximate idea of the quantitative reduction of prothrombin and he has constructed a graph of prothrombin time in diluted plasma which can be used for calculation. For practical use the suggestion of Alagath that the determination of the prothrombin time be repeated with plasma diluted with equal parts of physiologic saline solution when the clotting time of the undiluted plasma is less than forty seconds is a valuable one. If there is no marked increase in prothrombin time in the diluted material one may safely assume that the quantitative reduction in prothrombin is not great.

Quick's method may of course be criticized on the noted that the addition of various substances to normal plasma may cause prolongation of coagulation time when this method is used and, therefore, argue that

TABLE II

the observed changes do not necessarily indicate a deficiency of prothrombin. So far as the jaundiced patient is concerned, however, the results of the method appear to be satisfactory correlated with the tendency to bleed, a matter which is the principal concern of the clinician. The prothrombin time in a case of obstructive jaundice with hemorrhage rises steadily, as is illustrated in Fig. 1. In spite of repeated transfusions of blood, the prothrombin time in this instance continued to rise and remained elevated until death, which was due to massive intestinal and intraperitoneal hemorrhage.

Dam and Glavind recently have described a method of determining blood coagulation in reference to prothrombin; they have not as yet published a full account of the physiologic basis for this procedure but if their contentions that this method measures the concentration of prothrombin are correct their test gives values which parallel those obtained with Quick's method.

Warner, Brinkhaus and Smith (22) have outlined an elaborate quantitative method for determining the concentration of prothrombin and have employed it extensively in their clinical and experimental studies. With this method the concentration of prothrombin is determined by measuring the second phase of the normal coagulation process, the thrombin formed by prothrombin then being titrated by a method of serial dilution. By using this procedure Smith and his associates have demonstrated that bleeding occurs when the concentration of prothrombin reaches a level of approximately 20 to 30 per cent of the normal; as long as the level remains above this point, no marked prolongation of coagulation time occurs. This establishment of a "critical level" explains why patients with jaundice suddenly and unpredictably begin to bleed before or following operation, since even a small depletion of prothrombin in a patient whose total supply is low might presumably bring the level below the point required for formation of a clot. The quantitative method, unfortunately, is better adapted to a

Fig. 3. The effect of Vitamin K alone and Vitamin K with bile on the prothrombin time of a patient with obstructive jaundice.

research laboratory than to general clinical use and is subject to the difficulties inherent in a method employing tissue extracts and serial dilutions. Our experience with it has been limited but in general it confirms Smith's (22) contentions as to the value of the method. The relations existing between the prothrombin time as measured by Quick's method and the quantitative values for prothrombin are reciprocal, at least as the "critical level" is approached, the prothrombin time rising as the value for the concentration of prothrombin falls. A comparison of these figures in a few selected cases is given in Table II.

EFFECTS OF ADMINISTRATION OF VITAMIN K

We have administered to more than thirty patients, most of whom had obstructive jaundice, concentrates containing Vitamin K prepared from putrefied fish meal, together with bile salts or human bile obtained from a biliary fistula. This vitamin preparation was tested on K-avitaminous chicks and found to be protective in doses of 10 to 80 mg. per kilogram of diet.* It is the usual practice to give orally a daily dose of 200 to 1,000 mg. of the material containing Vitamin K, together with bile salts in doses of 1,000 to 4,000 mg. This is probably neither the minimal effective dose nor the optimal one. In some cases human bile that was obtained from biliary fistulas has been given instead of bile salts; it was mixed with cold pineapple juice and given by mouth in doses of 75 to 150 cc. before each meal. In certain cases in which the

patients were very ill and in which a more rapid effect was essential, bile and Vitamin K have been mixed and given through a tube, directly into the stomach or duodenum. A typical response of both prothrombin time and the concentration of prothrombin to Vitamin K and bile when administered together is illustrated in Fig. 2. This effect has been obtained repeatedly, the prothrombin time decreasing to within normal limits within a period of twenty-four to seventy-two hours and the prothrombin itself showing a quantitative increase. Active bleeding has at the same time been controlled in several instances. Warner and his collaborators (23) have independently obtained similar results in clinical practice with a petroleum ether extract of alfalfa meal, as determined by quantitative studies on prothrombin and by clinical observation.

It was obviously desirable to study separately the effects of Vitamin K and bile on prothrombin time in order to determine their relative protective values. In rats with external biliary fistulas Greaves and Schmidt have been able to increase the concentration of prothrombin in whole blood by administering massive doses of Vitamin K. However, as illustrated graphically in Fig. 3, one patient was given Vitamin K in large dosage for one week without any significant alteration in the prothrombin time and not until bile was administered with the Vitamin K was there a reduction of the coagulation time to within normal limits.

The effect of bile on prothrombin time remains to be considered. Judd and Wangenstein have each administered bile obtained from biliary fistulas to certain jaundiced patients with the hemorrhagic tendency and have noted that bleeding was markedly decreased or stopped. Hawkins and Brinkhous have obtained similar effects by the oral administration of bile to dogs with external fistulas who were bleeding actively. We have observed one patient with obstructive jaundice that was due to carcinoma of the pancreas who was able to take an adequate diet but who had complete biliary obstruction as shown by examination of the stools and duodenal contents. Following one week of the daily administration of fresh, alkaline bile which was obtained from biliary fistulas, there was a gradual fall in the prothrombin time to a normal level. The patient was then subjected to cholecystgastrostomy and the prothrombin time remained normal throughout the postoperative period (Fig. 4). These observations ap-

Fig. 4. The effect of bile alone on the prothrombin time in a case of obstructive jaundice.

*We are indebted to Mrs. Clementine Peirce Dann of the Abbott Laboratories, Chicago, and Dr. J. L. Bollman for bio-assay of this material and for their assistance in determining the protective effect of bile and other substances mentioned in the text.

Fig. 5. Postoperative rises in prothrombin time (two cases). These occur even when bile is entering the intestine and when the concentration of serum bilirubin is decreasing.

near to indicate either that bile serves chiefly as a carrier for the fat-soluble vitamin across the membrane of the intestine or that it has in itself some protective effect. It is, of course, known that human stools and those of chicks with K avitaminosis contain the vitamin, which presumably is formed by putrefactive organisms in the intestine. This would explain the source of the vitamin in a case such as that which has just been described. Biologic assays on chicks have shown that human bile obtained from biliary fistulas is weakly protective, presumably because of its high bacterial content and putrefactive processes. In one collection of human bile which was assayed and found to be protective, large numbers of *Bacillus aerogenes* were found growing in nearly pure culture; these organisms have since been shown to contain the protective substance. When a similar lot of bile was collected in acid and immediately autoclaved, it was found to have no protective activity. The evidence, therefore, indicates that bile acts as a medium for transport of the vitamin and has, per se, little antihemorrhagic activity. We have not administered bile alone to a patient who was not ingesting food, nor is there any entirely satisfactory experimental evidence on this point.

CARE OF JAUNDICED PATIENTS BEFORE AND AFTER OPERATION

The method of preoperative preparation of jaundiced patients has been indicated in an earlier paragraph. The administration of bile, bile salts, and Vitamin K has been continued in each instance until either the prothrombin time or the concentration of prothrombin has reached normal limits; the time required was usually short unless marked hepatic injury was present. An adequate diet and the administration of d-glucose intravenously are, of course, still essential in preoperative care. Although one's surgical colleagues may not be inclined to agree, there appears to be little reason to employ preoperative transfusions unless the patient is anemic, since the effects of added blood on either the prothrombin time or on active bleeding are very transient. The greatest danger of hemorrhage following surgical operation for the relief of obstructive jaundice usually occurs between the third and ninth day after operation. This usually is evidenced by a rise in the

prothrombin time, which seems to occur with considerable regularity following operation (Fig. 5). The effect of operation is often sufficient to decrease the concentration of prothrombin in the plasma below the critical level with a corresponding rise in prothrombin time. Whether this is a result of injury of the liver resulting from anesthesia or is due to the loss of blood at operation is not known. Postoperative bleeding may begin as a slight oozing from the wound or, gums, or as hematemesis or melena; it also may become generalized and severe with very little warning. Under such circumstances transfusions of blood are indicated; their effect is to supply a small quantity of prothrombin for emergency use; this exerts its effect for only about six or twelve hours, if at all. During this interval, the administration of Vitamin K and bile may be resumed, preferably by means of the intragastric or duodenal tube. Often, the drop in prothrombin time and the cessation of bleeding which follow are so rapid as to suggest the activity of an enzymic mechanism (Fig. 6). In addition to these two forms of treatment, the importance of beginning an adequate food intake as soon as possible is obvious since the reestablishment of normal biliary flow into the intestine and the restoration of a normal state of nutrition are the ultimate considerations required for cure of the hemorrhagic state. The administration of the vitamin and bile salts should be continued until the concentration of serum bilirubin is within reasonable limits and until the stools contain bile and the prothrombin time is normal.

One great desideratum for postoperative care is the preparation of Vitamin K in a form suitable for intramuscular or intravenous injection. This would avoid the difficulties and dangers of oral administration and undoubtedly would accelerate the restoration of lost prothrombin. The material which we have used is

Fig. 6. The effect of Vitamin K and bile on the prothrombin time following cholecystectomy for carcinoma of the pancreas. In this case bleeding stopped following the institution of this treatment.

prepared from putrefied fish meal and is unsuitable for injection, but Dam and Glavind recently have prepared an extract of spinach which can be injected and which has a demonstrable effect on the concentration of prothrombin. When this becomes available one great handicap in the treatment of active bleeding should be easily overcome.

SUMMARY AND CONCLUSIONS

Evidence has been presented to show that oral administration of a fat soluble vitamin and bile salts will increase the concentration of prothrombin and thereby reduce the clotting time of the blood, as measured by both direct and indirect methods. It appears that the vitamin alone will not accomplish this result if bile is excluded from the intestine, while bile or bile salts have some definite effect, presumably because these substances facilitate absorption of the vitamin which is already present in the intestinal tract. The question naturally arises as to why bile alone cannot be used in the preoperative and post-operative treatment. The first reason is, of course, that the prothrombin time may continue to rise postoperatively, even when bile is flowing freely into the intestine. As Warner, Brinkhous and Smith (23) have shown, the administration of Vitamin K greatly accelerates the restoration of prothrombin in such cases. The second is the inadequate food intake which is common to most jaundiced patients and which may of itself lead to depletion of the amount of Vitamin K in the digestive tract. The third factor has to do with the ability of the liver itself to convert the protective material into prothrombin. There is considerable clinical evidence to show that in the presence of injury of the liver larger amounts of Vitamin K are required to achieve the desired effect. Presumably, the chemical laws governing mass action are operative in this connection. A good deal of future experience will be needed before a definite statement as to the indications for and the limitations of this treatment can be established, but for the present it may be said that it offers considerable hope for the ultimate control of the hemorrhagic diathesis in jaundiced persons.

DISCUSSION

DR. I. S. RAVDIN (Philadelphia, Pa.): The paper by Dr. Snell and his associates is an extremely timely one.

For nearly eighteen years surgeons have been filling their patients full of various calcium salts in an attempt to control the hemorrhagic tendency of the jaundiced patient. In 1929, when we stated from our clinic that calcium salts were useless in the jaundiced patients, we were doubted. The recent investigations of Dam, Greaves and Schmidt, Quick, and those of Dr. Snell's associates at the Mayo Clinic, add an interesting chapter to the problem.

We have obtained a crude source of Vitamin K from the American Butter Company in Kansas City, Missouri, and we have used that for a period of several months. From 1922 to 1929 the incidence of hemorrhage of all degrees in jaundiced patients operated upon in our hospital was 22 per cent; from 1929 to 1933, the incidence of hemorrhage of all degrees was 20 per cent, and from 1933 to 1937, the incidence of hemorrhage was 21 per cent. The mortality in the meantime reduced from 22 per cent to 5 per cent.

It merely meant that we were taking better care of our patients prior to operation and better care of them after operation, which reduced the mortality from operations on jaundiced patients, but, nevertheless although the extent of the bleeding was probably less, the incidence of hemorrhage was as high in 1936 as in 1922. I am happy to say that since our experience has been exactly similar to that Dr. Snell has reported, we have not had a fatal hemorrhage since we began the use of Vitamin K.

It is easy to explain why those patients operated on for duct obstruction, in which bile is flowing into the intestine, either in the method Dr. Snell described or in the method which we reported last year the vitamin may prove inadequate. Such bile contains no bile salt as was shown by Green, Fredrickson, and Walters some years ago, and confirmed by my associates. Under such conditions the amount of Vitamin K absorbed from the intestine may not be adequate to bring the prothrombin time to normal even though bile should be flowing to the intestine.

We have been using hogs' bile, but it seems to me it makes little difference which one uses. Dr. J. E. Rhoads of my service has been using lyophilized hog and human bile and desoxycholic acid.

The use of Vitamin K plus bile, as described by Dr. Snell in this paper, adds a most important chapter in the pre-operative preparation and the post-operative care of the jaundiced patient. Whether one believes it is entirely associated with prothrombin levels or not, the fact remains that prior to the introduction of Quick's method we had no means of telling which patients would or would not bleed. We now have a method of studying and preparing patients before operation and even though the theoretical basis may prove in part to be wrong, the practical application of it is of great value.

DR. ANDREW C. IVY (Chicago, Ill.): Mr. President, and Ladies and Gentlemen: This, obviously, is a very important piece of work, and I have no suggestions or criticisms to offer. I should like to call your attention to certain

D. Bile salts are essential for the absorption of Vitamin D from the intestine. They are also essential for the absorption of Vitamin A. Bile salts also appear to be necessary for the absorption of Vitamin K.

Several years ago Dr. McNealey of Cook County Hospital, Chicago, came to me with the problem of the bleeding tendency in jaundice, and I told him that there might be some connection with the discovery that had just been made showing that bile salts are essential for the absorption of D. I suggested that they give 10,000 units for D three times a day to their patients. I suggested that they use the Duke bleeding time and study the ordinary prothrombin time as it was then performed, but they found no correlation between the clinical bleeding tendency and those determinations. Knowing from the literature that in the hepatic insufficiency of long standing jaundice there may not only be a disturbance of the coagulability of the blood but also of the capillaries, I suggested they place a sphygmomanometer cuff on the arm and raise the pressure to 40 degrees of mercury, causing venostasis, which would tend to put additional stress upon the hemostatic mechanism. When that was done, they found a number of these patients would bleed abnormally long, over a period of four, five, up to ten or fifteen minutes. It was found by controlled operations, that such a patient when operated would bleed post-operatively or manifest serious post-operative disturbances.

When viosterol was given these patients before the operation, along with bile salts, the bleeding time would come back to normal; if the patient's bleeding time did not come back to normal as a result of the administration of the Vitamin D, the patient if operated would die or have a very stormy post-operative convalescence; in other words, the failure to respond to D—and I suspect the same observation will be made in regard to Vitamin K—is of prognostic value and will determine not only the surgical risk but also serve to determine the prognosis in a medical case of hepatic insufficiency.

I should like to ask Dr. Snell if he has observed any surgical or medical patients who have not responded well to Vitamin K; if so, there is another analogy between the action of K and D on the hemorrhagic tendency in jaundice.

There is one other point, one does not have a jaundiced patient to observe a prolonged bleeding time. We have been studying our medical students and each winter we pick out from four to six medical students in our classes who have a prolonged venostasis bleeding time, and they respond to Vitamin D. This past winter we had two women who, when punctured according to our technique not only bled abnormally long but also hemorrhaged into the subcutaneous tissues. The administration of D took care of that disturbance.

DR. RAVDIN: I am interested in what Dr. Ivy has to say. Following the publication of the papers from Dr.

DR. ALBERT M. SNELL (closing the discussion): I am grateful to Dr. Ravdin and Dr. Ivy for their comments and remarks.

I do not want to imply that the only thing we do to prepare a jaundiced patient for operation is to give Vitamin K and bile salts. We insist on the usual pre-operative treatment with glucose and an adequate, high carbohydrate diet, factors which are as essential as they ever were. Cereophyl (formerly called vitola) has been tried in a limited way and has been found to be protective when given to avitaminous chicks in an amount of 100 mg. per kilogram of diet. This assay applies to only one batch but Vitamin K. We are hoping to make concentrates of Vitamin K by extraction of cerophyl with petroleum ether but, until that is done, it is feasible to give the dry powder by mouth.

I am thankful to Dr. Ravdin for mentioning the low concentration of bile salts in the usual specimen of bile obtained from fistulas after operation. No doubt the post-operative inhibition of formation of bile salts has something to do with the post-operative rise in prothrombin clotting time. I presume that the absorption of Vitamin K, in respect to concentration of bile salts in the intestine, follows the laws of mass action. If there is a small amount of bile salts and considerable Vitamin K, a limited rise is obtained; if there is a good deal of both a larger rise results, which I think is an adequate reason for giving large doses of both the vitamin and bile or bile salts, post-operatively.

Failure to respond to treatment with Vitamin K has not been noted if patients have had adequate amounts of bile in the intestine, but we have seen two patients with atrophy of the liver who required large doses and who did not give a too satisfactory response. One man died in hepatic coma, with some bleeding which was hardly sufficient to be a contributing cause of death. I presume the hepatic factor is very important in the utilization of vitamin K to form prothrombin.

Our experience with the Ivy bleeding time has been somewhat limited but by means of it we have not been able to identify all of our bleeders in advance. I think the test deserves a much greater trial than we have given it to date.

Ivy's department, we began the use of what is known as the Ivy bleeding time. As Dr. Ivy has stated we often found prolonged bleeding times in such patients, but we obtained no information as to which patients might bleed and which might not bleed after operation. That is, we did not find it an accurate method of telling us which patients would bleed; patients with perfectly normal bleeding time with the cuff applied showing 40 millimeters of mercury, at times bled seriously after operation.

For a period of several years our patients were fed Vitamin A and D in adequate and abundant amounts, and the incidence of bleeding, in all patients remained approximately the same. Since the introduction of Vitamin K, and bile feedings the incidence has declined sharply.

The Value of a Combined Study of the Newer Laboratory Test in the Differential Diagnosis of Toxic and Obstructive Jaundice Including Blood Phosphatase, Cholesterol Partition, Galactose Tolerance and Glucose Tolerance*

By

HARRY SHAY, M.D.

and

PHILIP FIEMAN, M.D.

PHILADELPHIA, PENNSYLVANIA

ALTHOUGH in many instances the differential diagnosis between obstructive and toxic jaundice may be made from the clinical picture alone, it is true that frequently the clinician is forced to seek help in the laboratory. Laboratory procedures subject to difficulties imposed by the peculiar physiology and tremendous reserve of the liver often lose value through attempts to give them too broad a scope. Realizing that any test purporting to help differentiate between toxic and obstructive jaundice must involve some function of the liver and must, therefore, be subject to the above limitations, we decided to combine the various tests that have been proven of some value in jaundice; to do all the tests dependent upon blood examination on the same sample of blood; and to repeat these tests at frequent intervals during the course of the jaundice, extending them whenever possible into the recovery period. By this procedure we hoped to discover the limitations of individual tests; to determine whether individual limitations were dependent upon different factors in the course of the jaundice; and to counteract the limitations imposed by any one test through the combinations of several tests. We hoped, too, to establish more certain criteria upon which to make a differential diagnosis between toxic and obstructive jaundice.

Unfortunately, the laboratory is not the magic slot machine it is sometimes asked to be. This is especially true when utilizing it in the study of jaundice. The variable degree and duration of superimposed obstruction in the finer bile canaliculi in toxic jaundice, coupled with a possible superimposed infection or hepatic cell damage from prolonged obstruction in obstructive jaundice make for a mixed and very often a changing picture.

We have used the quantitative van den Bergh to follow the intensity of jaundice and have compared and contrasted our results with blood serum phosphatase by the Kay Roberts method (1); the total cholesterol and cholesterol esters by the method of Bloor and Knudson (2); the galactose tolerance (3); and the glucose tolerance by the method of Jacobi (4).

GALACTOSE TOLERANCE

Bauer (5) first used the galactose tolerance test to help in the differentiation of obstructive and toxic jaundice. Widely used on the continent, it was not

until 1931 (6, 7) that interest in this test was stimulated in this country where numerous investigators have since confirmed its value.

In the human subject the utilization of galactose makes it ideally suited for testing hepatic carbohydrate function. Its use in obstructive and toxic jaundice, especially in the painless jaundice group of middle and later life, has been stressed (8). More recently because of the conversion of galactose to glucose and its special behavior both as to kidney threshold and utilization, we (3) have recommended that an output over three grams in the five hour test period be checked by fermentation with properly prepared yeast. The technique for the test, as well as the fermentation technique, has been described previously. Reports regarding its value in the differential diagnosis of jaundice have come from many clinics: Rosenberg (9), Schiff and Senior (10), Owen (11), Johnson (12), Tumen and Piersol (13) and Paulson (14) have all found the test of great value.

We have repeatedly stressed the fact that the physiology of the liver, with its tremendous reserve and excellent regenerative power, must put certain limitations upon any liver function test and especially upon one concerned with so vital a function as carbohydrate metabolism.

In obstructive jaundice not complicated by infection, the five-hour output after 40 grams of galactose is below 3 grams, while in diffuse acute parenchymatous liver disease, the output is usually above 3 grams. But in obstructive jaundice with superimposed infection and associated parenchymatous damage, the output of galactose can exceed 3 grams. In the same way, a toxic hepatitis may be mild enough not to alter the carbohydrate function of the liver to cause an excretion of over 3 grams. During the ascent of a severe grade of toxic hepatitis, or in the recovery period, the galactose tolerance may again be normal. A repetition of the test and an interpretation in the light of the clinical and blood bilirubin findings will usually indicate the true state of affairs. No laboratory test will yield 100% results and the galactose tolerance test will occasionally yield a wrong reading for which no suitable explanation can be found; but usually apparently wrong readings if interpreted blindly, will call for an indictment of the observer more often than of the test.

Our present studies indicate all the cases in point

*From the Gastro-Intestinal Division of the Medical Service of Dr. A. I. Rubinstein, Mt. Sinai Hospital, Philadelphia, Pa.

bilirubin. In this instance the return of the galactose test to normal more closely parallels the rise in cholesterol esters.

CHOLESTEROL PARTITION

Although Austin Flint, Jr. (15), as early as 1862 described "a new excretory function of the liver which consisted in removing cholesterol from the blood" and attempted to utilize the fate of blood cholesterol to differentiate between obstructive jaundice and suppression of bile, it was not until better methods of cholesterol analysis had been developed that the necessary impetus for detailed studies of cholesterol metabolism was achieved. In the present study, we are concerned only as it relates to jaundice. Thannhauser (16) who in our opinion offers the most workable hypothesis, says the liver is the main excretory organ of cholesterol and regulates the relative content of the blood in both cholesterol and cholesterol ester. Further, Thannhauser and Schaber (17) attributed the drop in cholesterol ester in hepatic cell damage to a disturbance in liver synthesis and hydrolysis of cholesterol esters. They consider this reversible reaction dependent upon the enzymes of the liver cells, which are disturbed in diffuse parenchymatous lesions. Sperry

and graphically show what we have previously said about the importance of doing this test early in the jaundice. Thus in Cases 1, 2, 3 and 10, all cases of obstruction, we find readings below 3 grams. Unfortunately, in Cases 3 and 10 we did not obtain galactose readings at the time diffuse liver damage supervened. An excretion of over 3 grams at these times would have been the expected result. Cases 4, 5, 7 and 8 show the typical results obtained with the galactose tolerance test in toxic jaundice. Case 6 illustrates what may happen if the galactose tolerance test is done when liver cell recovery has already set in, although the jaundice is still quite marked. The low galactose output on the 10th day of jaundice if interpreted independently could readily be taken as a failure of the test. However, both the rapidly falling blood bilirubin and rising cholesterol esters indicate that the recovery and rising cholesterol esters indicate that the recovery, too, that liver cell recovery, as indicated by a return of galactose utilization to normal, varies in different cases. Thus in Case 4, the excretion of galactose drops only gradually in comparison with the drop in blood

Case 1

Case 2

Case 3

jaundice may be and then consider deviations and their explanations.

In uncomplicated obstructive jaundice, the expected result is hypercholesterolemia with the maintenance of a normal cholesterol ester ratio of 50% to 70% of the total cholesterol.

Case 1, a carcinoma of the head of the pancreas, was followed for a little over a month before operation. The total cholesterol ranged from 325 to 375 mgms. per 100 cc. but was accompanied by a proportionate rise in cholesterol ester so that the ratio is maintained between 50% and 70%.

Hypercholesterolemia with obstructive lesions of the biliary tract was observed by Austin Flint, Jr. (15), seventy-five years ago. Rothschild and Felsen (23) as well as Stepp (24) noted a direct relationship between the degree of jaundice and the cholesterolemia in pure, uncomplicated cases of obstructive jaundice. This is usually true when the obstruction is stationary. However, in an uncomplicated obstruction in which the obstruction decreases, this relationship does not hold.

Case 2 illustrates this feature. An uncomplicated duct obstruction due to a stone which was relieved spontaneously, showed a rising blood cholesterol and esters when the quantitative van den Bergh was dropping rapidly. A similar change is frequently seen in the recovery period from toxic hepatitis as well.

Our findings corroborate those of Epstein and Greenspan (25) who failed to see an absolute parallelism between the degree of hyperbilirubinemia and the hypercholesterolemia in their group of obstructive jaundice.

Rothschild and Felsen (23) recognized that an infection altered the direct relationship between the increase in cholesterol and the degree of jaundice. This was recently stressed by Wilkinson (26) and is illustrated by Case 3. In this instance, there was again a common duct stone obstruction, but infection and high fever had supervened. Here we saw a rapidly rising blood bilirubin accompanied by a falling total cholesterol and an even more rapid decrease of cholesterol esters so that the ratio was considerably below normal. Such a rising blood bilirubin and dropping cholesterol and esters are usually of serious prognostic import, especially in cases of obstructive jaundice. In this instance the patient died 2 days after the last group of readings were obtained. (See Case 10 in which instance the patient also died).

Our data in conformity with those of Epstein and Greenspan (25) do not support the opinion of Burger and Habs (20), Gardner and Gainsborough (22) and Stroebe (27) that the hypercholesterolemia in obstructive jaundice is caused mainly by an increase in free cholesterol and that ester is not proportionately raised. Their interpretation that this results from the absence of bile in the intestines which in turn is responsible for a reduction of cholesterol ester absorption by the intestine, is also not supported by experimental evidence. Hawkins and Wright (28) found the absence of bile in the intestines and a faulty absorption of fat in biliary fistula dogs did not result in a dissociation of the ester ratio. Furthermore, Rosztochy (29) in rabbits and Stern and Suchantke (21) in dogs found an increase in both free and ester cholesterol after common duct ligation.

In toxic hepatitis, the typical picture is a normal or moderately increased total blood cholesterol with a decrease in esters which results in a lowered ratio. Here

(18), Salomon (19), Burger and Habs (20), and others believe that the intestinal mucosa is the main avenue of excretion for cholesterol. Burger and Habs (20), Stern and Suchantke (21) and Gardner and Gainsborough (22) would rather consider the drop in esters the result of the failure of fat absorption. This necessitates the deesterization of combined cholesterol in the plasma to permit the utilization of the fatty acid.

Since the level of blood cholesterol is influenced by the variations in the functions of the pituitary, thyroid, gonads, pancreas, and adrenals as well as by many conditions not directly related to the function of these glands, the application of cholesterol studies to the problem of general liver disease would be subject to many limitations. However, restricting its use to the changes produced in jaundice, the study of the cholesterol partition is a valuable diagnostic aid.

To simplify discussion let us consider what the expected results in uncomplicated obstructive and toxic

Case 4

a divergence between the intensity of the jaundice and the concentration of blood cholesterol is the rule. Although Feigl (30) first observed low cholesterol ester values in acute yellow atrophy, its clinical significance was not appreciated until Thannhauser and Schaber (17) eight years later recognized that it represented a disturbance in the ability of the liver to regulate the level of the free and combined cholesterol of the blood. Their findings have been confirmed by a number of investigators and especially by Epstein (31). A typical result in toxic hepatitis is seen in Case 4. Here with the intense icterus, the normal total cholesterol is accompanied by a marked depression of the esters so that the ester ratio was reduced to less than half of normal. This case also illustrates what is commonly seen in recovery in toxic hepatitis. There is usually a rise in both total cholesterol and esters often to above normal limits with a later return to normal (see Cases 5 and 6).

In our experience, a rise in esters was accompanied by a fall in blood bilirubin. While, as previously noted, a divergence between the total cholesterol and the intensity of jaundice was the rule, a close inverse relationship of changes in blood bilirubin and cholesterol ester ratio is usually seen. Thus, in the course of toxic hepatitis an increase in jaundice is usually accompanied by a decrease in ester ratio, while the reverse is true in the recovery period. The rise in ester ratio

has been very useful in establishing the recovery period in toxic hepatitis. This is well illustrated in Case 5.

In mild cases of toxic hepatitis cholesterol esters may fail to show a diagnostic drop at any period of the jaundice. Case 7 is illustrative of such an instance. Further, it shows in addition to a hypercholesterolemia a most striking rise in cholesterol at the second examination on the 10th day of jaundice in the recovery period. There was, too, a sharp rise in esters. This may represent an exaggerated rise in the recovery period previously mentioned, but we have never seen anything so sharp before. Occasionally, too, we saw results which we were unable to explain. Thus, in Case 8, a case of toxic hepatitis, the hypercholesterolemia and normal ester ratio on the 3rd day of jaundice were followed on the 5th day by a very sharp drop in both, especially the esters, despite the fact that recovery was taking place.

In Case 9 we had an opportunity to follow the course of the jaundice in two attacks of toxic hepatitis. In both, the characteristic changes for cholesterol and esters occurred.

PHOSPHATASE

Roberts (1) in 1930 was the first to report an increase in plasma phosphatase in jaundice. Three years later he (32) reported a series of 52 cases which convinced him that the phosphatase level in the blood offered a means of differentiating between obstruc-

Case 5

tive and toxic jaundice. Since then many reports on the test have appeared: with some investigators as thoroughly convinced as Roberts of its value; with others just as certain that it is without merit. Allowing that both groups of results are equally reliable, one may assume from experience with liver function tests that both groups of investigators are correct, within certain limits. Both, however, fail to take cognizance of the frequency with which obstructive jaundice has a superimposed toxic factor as well as the commonly occurring phase of bile canalicular obstruction in toxic hepatitis. These superimposed phases may diminish, neutralize, or completely conceal the effect produced by the basic type of the jaundice actually present.

It is our belief that no test concerned with changes in liver activity incident to jaundice can ever be properly interpreted without a knowledge of the limitations thrust upon it by the liver itself. These limitations for the phosphatase have not as yet been established. The test is further beset because there is no single accepted technique, a fact that makes reported results not entirely comparable. Furthermore,

the higher and variable normal level in the young further complicates the interpretation of phosphatase readings in jaundice in this group.

Roberts (32) found that in jaundice due to mechanical obstruction of the bile ducts the blood phosphatase showed a striking increase (10.9 to 22.9 units); in jaundice of the toxic or infective type the figures were either normal or slightly raised (3.7 to 8.9 units, except for one case of catarrhal jaundice in a child). Meranze and Meranze (33) in an earlier report from their laboratory, using the Kay Roberts method, found figures that are identical with those obtained by Roberts (32). In this series, using the Kay Roberts method, we obtained consistently higher readings. With the results we have obtained, the limits for the toxic range reported by Roberts must be raised if the readings are to be of any value. These results fit in best with those reported by Freda K. Herbert (34) and have led us to consider readings below 16 units as due to toxic hepatitis; figures above 20 units to obstructive jaundice, and those between 16 and 20 units to belong in the indeterminate zone. The interpretation of all figures, however, is dependent not only

Case 6

upon the clinical picture, but upon the results of the test repeated at 2 to 3 day intervals over a period of a week.

Since Meranze and Meranze have obtained lower readings with the same method, and frequently on the same sample of serum in which higher readings were obtained by us, we believe it extremely important for the present that each laboratory using the phosphatase test establish its own limitations for the range of toxic hepatitis until such time as there is a standardized method. Otherwise, a test which appears to have some usefulness in the differentiation of toxic and obstructive jaundice may fall into disrepute.

In general, reported readings have been higher in the obstructive jaundice than in the toxic group. Some, however, have seen as wide a range in both groups. Thus Greene, Shattuck and Kaplowitz (35) have reported figures for plasma phosphatase in obstructive jaundice ranging from 11.6 to 63.2 units, and in hepatitis from 8.4 to 72.2 units. Fiessinger and Boyer (36) likewise found that a considerable increase in blood phosphatase was not limited to the obstructive form

of jaundice. Cantarow (37) has reported similar findings. Morris and Peden (38) found overlapping of the values in the two groups of jaundice—a result similar to that reported by Anderson (39).

Herbert (34) in her data shows an association of high phosphatase figures with obstructive jaundice, but indicates that in a certain proportion of toxic or infective cases moderate rises, or rarely, marked rises in the plasma phosphatase can occur. Thus in the obstructive group she found that the majority of values were above 20 units while only 2 of 22 cases of toxic jaundice were above this figure. This in general is more nearly in accord with our results.

One must remember that here, too, diffuse hepatic damage in obstruction (Cases 3 and 10) can cause a drop in phosphatase in spite of a rising icterus while the obstructive phase in toxic hepatitis may be so marked as to produce readings even in adults in the indeterminate zone (Cases 4 and 5) and at times actually above 20 units (Case 5).

As previously pointed out, the higher normal figures seen in the young may be responsible for the usual

Case 7

Case 8

higher phosphatase figures seen in toxic hepatitis in young people.

This facile explanation must not be accepted too readily because, as indicated by Case 9, when followed long enough to establish complete recovery, we find that the normal phosphatase for this child of 15 years was in the normal adult range. It is our impression that phosphatase readings in toxic hepatitis run higher in children than in the adult and to a degree that cannot be accounted for by the usually higher normal phosphatase reading alone. For this reason especially do we believe it important not to attempt at present to make the toxic hepatitis zone too narrow. Furthermore, since it has not been established at which age the phosphatase drops to adult levels; whether this is a sudden or gradual process; and whether it occurs at the same time for all individuals, more flexible standards at this time will certainly be more useful in establishing the value of the test.

The mechanism for the larger increase of phosphatase in obstructive jaundice and the usual slight increase in toxic jaundice is as yet not clearly explained.

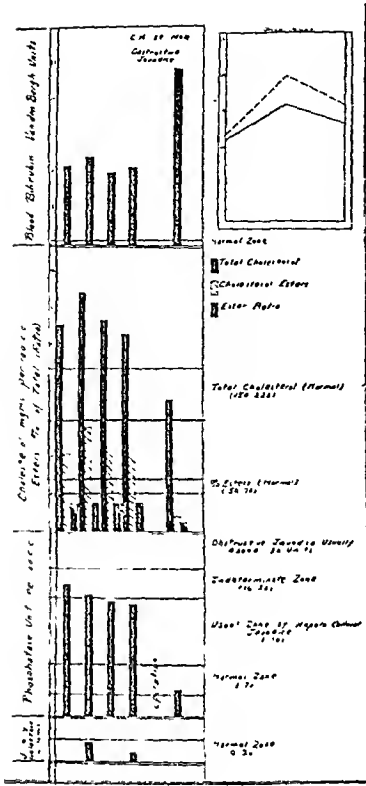

The rise in the former type has been attributed to the re-absorption into the blood stream of bile which has a high phosphatase content. General clinical experience and the results of experimental obstructive jaundice appear to support the view that the liver acts as an organ for excretion of phosphatase, although Austoni and Coggi (40) and more recently Morris and Peden (38) have suggested that the height of the blood phosphatase in jaundice depends upon an impaired supply of calcium to the bones incident to a defective absorption of calcium in jaundice. This factor remains to be determined. Although Bodansky and Jaffe (41) felt that the liver was an important source of plasma phosphatase, more recent experiments of Armstrong and Banting (42) clearly indicate that the liver does not contribute any of this enzyme. They are of the opinion that the bones constitute the sole source of serum phosphatase. This is in accord with views voiced by Herbert (34) and by Anderson (39).

While it would be helpful to visualize an increase of blood phosphatase in jaundice as an expression of obstruction whether canalicular or extrahepatic as suggested in the views of Herbert (34) and of Anderson (39), our present serial studies do not permit such an interpretation. Thus Case 3, an obstructive jaundice at the thirty day period when diffuse hepatic damage was superimposed, had a sharp drop in phosphatase in spite of the sharp rise in jaundice. Case 10 illustrates the same result. Not infrequently, too, one sees a definite rise of phosphatase in the recovery period of toxic hepatitis. Cases 4, 6, 7, and 8 in the light of the blood bilirubin curve could hardly be attributed to any increase in obstruction. It is also difficult to attribute those changes to changes in calcium absorption at those times. An adequate explanation for all the changes in the blood phosphatase in jaundice is still to be found.

Illustrated in this paper are 148 readings of phosphatase in jaundice. Thirty six in obstructive jaundice and one hundred and twelve in toxic hepatitis. Using the standards employed in this paper, nineteen of the 36 readings gave evidence of the obstructive nature of

Case 9

Case 10

the jaundice (i.e. readings above 20 units). Of the remaining seventeen readings, six fell in the indeterminate zone between sixteen and twenty units while eleven were below sixteen. It must be considered, however, that of these eleven readings, five were taken when the bilirubin level was near normal in the recovery period from a stone obstruction. Three represented low phosphatase readings incident to superimposed hepatitis in obstruction. In the pure obstructive group, then, the phosphatase reading was definitely informative.

The toxic jaundice group, while represented by 112 readings, only 70 can actually be considered because the remaining forty-two readings were taken in practically the recovered period. These would naturally, fall in the low level zone. Of the 70 readings when definite jaundice was still present, 38 were below 16 units, 21 between 16 and 20 units, and 11 above 20 units. It must, however, be indicated that of the 21 between 16 and 20 units, ten instances occurred in children 15 years and younger, and 11 occurred in adults, and of those readings above 20 units, 8 occurred in children and only 2 in adults. Summarizing, readings above 20 units obtained under the conditions employed in this study are in favor of obstructive jaundice; readings below 16 units, provided one can rule out the recovery period of an obstructive jaundice, are in favor of a toxic hepatitis. In obstructive jaundice due to superimposed infection low phosphatase readings may be obtained and in the obstructive phase of toxic hepatitis readings above 16 and even above 20 units may result. The latter, however, occurring most often in the first

two decades of life. The impression is that although the normal blood phosphatase in young people may be on the average higher than in adults, there is apart from this a tendency to higher phosphatase values in toxic jaundice in the young as compared with adults.

GLUCOSE TOLERANCE TEST

Recently Jacobi (4) (43) suggested that the glucose tolerance test be used in the differentiation of toxic and obstructive jaundice. The many factors involved in the blood sugar response to a test load make us doubt whether the application of the glucose tolerance test can be so closely circumscribed. Jacobi, however, reported some striking differences in the results obtained in the two types of jaundice. We have, therefore, used this test in the study of our cases of jaundice. While our experience is as yet not extensive enough to permit the expression of an opinion regarding its value, our results have thus far been similar to his. While we believe a much larger experience will be necessary to establish its usefulness and especially its limitations, we do think it worthy of further investigation.

Jacobi described for toxic jaundice two types of curves following the ingestion of 100 grams of glucose. He recommends taking fasting blood sugars: one forty-five minutes after the ingestion of the glucose and one at two hours. In the flat curve, the rise in blood sugar is very slight throughout the period following the intake of the glucose. This type is exemplified especially well in Case 8. The second type shows a low fasting blood sugar followed by an early high rise and a subsequent fall to the normal or fasting level at the end of the 2nd hour period. Case 9 on the

Case 11

Case 12

14th day of jaundice gave a typical curve. If the test is repeated often enough in the course of the jaundice, both types of curves are found, as illustrated in Case 9.

In common duct block by stone stricture or suppuration, Jacobi described a sugar tolerance response characterized by a gradually ascending curve. Beginning with either a normal or elevated blood sugar, the curve rises steadily so that the two hour figure is always considerably higher than that of the fasting blood sugar. This type was seen typically in a case of common duct stone obstruction in Case 12. We have, however, encountered what would have to be considered typical obstructive curves in toxic jaundice as shown in Chart II and have seen the toxic jaundice type of curve in proven common duct obstruction as shown in Case 10. The latter results are not offered as evidence denying any value to the glucose tolerance test in jaundice. Rather, we wish to draw attention to the fact that many cases of jaundice will have to be studied in which the test is repeated frequently during the jaundice in order to determine what limitations the changing picture of jaundice will produce in the type of glucose tolerance curve.

SUMMARY

The use of any liver function test in jaundice should not be limited to a single determination. Furthermore, a combination of tests whose interpretation and limitations are reasonably well understood would certainly lessen the chance for error. It is our belief that mistakes in diagnosis between obstructive and toxic jaundice could be practically eliminated if the group of tests employed in this report are repeated approxi-

mately three times in the course of a week during any period of jaundice. By evaluating the results obtained with the clinical picture, one may with assurance determine the type of jaundice present. Furthermore, the various tests are influenced somewhat differently by the obstructive phase in toxic jaundice, and a superimposed toxic factor in obstructive jaundice. In general the results of the galactose tolerance test appear to parallel those obtained by a study of the cholesterol partition.

In some cases, Case 6 and Case 9, normal levels of galactose were reached before the return of the ester ratio to normal. In such cases the cholesterol partition seems to be the more sensitive of the two. In other instances, Case 4, the reverse appears to be the case. In still other instances, Case 7, 8, and 11 positive galactose tolerance readings were obtained when the cholesterol partition was entirely normal. The obstructive phase in toxic hepatitis does not appear materially to affect either the galactose tolerance or cholesterol partition while the phosphatase may at such times reach the indeterminate zone or even obstructive levels. This is especially important in adults (Case 5). On the other hand, both the galactose tolerance and the cholesterol partition are more readily affected than the phosphatase level by toxic changes superimposed upon obstructive jaundice. It has been our experience that a sharp drop in phosphatase level which accompanies a sharp drop in total cholesterol and esters in the presence of a rising blood bilirubin is of very serious import especially if occurring in obstructive jaundice (Cases 3 and 10) when it usually spells a fatal outcome. The exact value of the glucose tolerance test in this problem must be established by further work.

For those who may not have available fully equipped laboratories to carry out the elaborate chemical processes involved in the cholesterol and phosphatase determinations, the simple galactose tolerance test, if done properly early in jaundice and interpreted on the basis of the criteria laid down, still remains the most reliable single laboratory test in the differentiation of toxic and obstructive jaundice.

DISCUSSION

DR. HENRY L. BOCKUS (Philadelphia, Pa.): Mr. President, Ladies and Gentlemen: I was disappointed in Dr. Shay's paper because I was hoping that he would give me some opportunity to take exception to what he had to say, as I had no opportunity to read his paper before he presented it.

I think all of us here who have had a fairly wide clinical experience, know that there is a small group of cases of jaundice in which it is rather difficult to make a diagnosis without the use of certain laboratory methods. Clinical methods are good enough in possibly 75 per cent of the cases, but there are a considerable number in which we need other help.

I should like particularly to congratulate Dr. Shay for the manner in which he went about this study. I think the ability to visualize the results these tests carried out on a small group of cases from the beginning to the end of the course of jaundice means a great deal more than do group statistics attempting to state how valuable the galactose test is in a group of one hundred and fifty cases, or how valuable the hippuric acid test is, or any other single test.

Anyone who knows anything about liver physiology and jaundice, knows that the situation varies day by day and week by week, and it is only by careful measurement by a number of different methods, done at the same time, that one can actually arrive at a definite conclusion concerning the state of liver cell function and destruction at that particular time.

I have had very little sympathy with people who publish papers on large groups of cases without drawing attention to that fact.

Of course, all of us do not have a private laboratory at our disposal. Many of us cannot do all these tests on any given case, but I think you will gather from Dr. Shay's statistics here that if you select the galactose test early in the course and follow it through, and the cholesterol partition, and possibly a glucose tolerance test, you have information that is rather reliable in the great majority of cases.

I agree with Dr. Shay that the phosphatase test needs a little more study before its value is established in the differential diagnosis of jaundice.

I should like very much to have the President invite Dr. Rothman to discuss that phase of the subject, if he is here, because he has had a tremendous experience with it.

I should like to close by stating that I feel that this contribution that Dr. Shay has made has done more to clarify the question of differential diagnosis from the laboratory standpoint in these two types of jaundice, than perhaps any paper I have read.

(Dr. Rothman was called upon but was not present).

DR. HARRY SHAY (Philadelphia, Pa.): Mr President, I only wish to thank Dr. Bockus for his discussion. Since we are in complete agreement there is nothing to add.

A Proved Case of Recovery from Fatty Metamorphosis of the Liver After Treatment with Lipocaic*

By

DAVID H. ROSENBERG, M.D.

CHICAGO, ILLINOIS

IN 1924, Fisher (1), and Allan, Bowie, Macleod and Robinson (2), observed that depancreatized dogs treated with sufficient insulin to control the diabetic symptoms, developed signs of hepatic insufficiency, became insulin-sensitive, and died in a state of hypoglycemia within one to eight months. Necropsy studies revealed a marked fatty infiltration and degeneration of the liver as the principal or sole abnormality. By the addition of raw pancreas to the diet, Allan and his co-workers were able to prevent such hepatic changes and to permit survival for a long time. These observations have since been confirmed repeatedly by different investigators (3, 4, 5, 6). Accompanying the enormous accumulation of fat in the liver (consisting mainly of triglycerides [neutral fat]) (7), Chaikoff and Kaplan (8) reported a decrease in the whole blood lipids and, in most animals, a disappearance of the cholesterol esters.

The nature of the essential factor in raw pancreas has been the subject of extensive research. That this substance is not supplied by the pancreatic enzymes was indicated by the work of Hershey and Soskin (3) and others, and now seems conclusively demonstrated by the experiments of Prohaska, Dragstedt and Harms (6), who were unable to prevent the hepatic changes by the feeding of adequate amounts of fresh pancreatic juice. Hershey (9) and Hershey and Soskin (3) found that the daily administration of egg yolk lecithin prevents as well as cures the fatty metamorphosis of the liver, as shown both histologically and chemically, and permits survival of the animal for considerable periods of time. Best and his co-workers (5) confirmed this work, and found choline to be the effective component in lecithin. Betaine, similar to choline chemically, had an analogous effect (5c). Recently, Dragstedt, Prohaska and Harms (10) prepared a fat free alcoholic extract of beef pancreas ("lipocaic") which, when fed to depancreatized dogs, proved as effective orally as either raw pancreas, lecithin or choline, and which they believe to be a "fat metabolizing hormone," concerned in the normal transport and utilization of fat.

The application of these experimental observations to therapeutics in man was attempted by Judd, Kepler and Rynearson (11), who administered choline and betaine to two patients with fatty metamorphosis of the liver (biopsy) accompanied by hypoglycemia, but no beneficial effects were observed. Dragstedt and his co-workers (12) exhibited lipocaic to patients manifesting diabetes mellitus in association with hepatomegaly and noted a decrease in the size of the liver. A similar effect was observed by Grayzel and Radwin (12 a) in three cases of juvenile diabetes mellitus

treated with a pancreatic extract prepared according to the method of Dragstedt et al. In a presumptive case of fatty metamorphosis of the liver (? portal cirrhosis), Snell and Comfort (13) reported a rapid decrease in the size of the liver and an improvement in the hepatic function during the first twelve days of lipocaic therapy. Their patient had also received an increased carbohydrate diet both before and during such therapy. In no instance, however, have the effects of this substance been observed in a proved human case of fatty metamorphosis of the liver.

We have had the opportunity of administering lipocaic to a patient with marked fatty metamorphosis of the liver associated with diabetes mellitus, correlating the clinical observations with the results of liver function and glucose tolerance tests and with the gross and histologic appearance of the liver both before and after treatment. The findings are so striking as to merit this report.

CASE REPORT

J. S., a white female, aged 59, a housewife, was admitted to the Mandel Clinic on March 3, 1937, complaining of weakness and shortness of breath. For 4-5 years, she had noted a sharp, sticking pain over her heart, which pain appeared when she became emotionally upset or after working hard, and which was accompanied by dyspnoea. Three months ago, dyspnoea became more noticeable following exertion, and a rather striking degree of weakness was evident, both of which symptoms had persisted. She had gained 20 pounds (9.1 Kg.) in weight during the last six months without apparent increase in food intake.

Past History: During her first pregnancy, at the age of 23, she had gained 30 pounds (13.6 Kg.) in weight and noted the development of facial hirsutism. In the subsequent eight years, she gained an additional 20 pounds (9.1 Kg.), her weight remaining constant thereafter, until the onset of the present illness. In 1933, a hysterectomy was performed for the removal of uterine fibroids. The remainder of the history was non-contributory.

Physical examination revealed a rather obese, well developed individual who did not appear acutely ill. Dyspnoea and orthopnoea were conspicuously absent. There was an excessive growth of hair on the face and to a lesser extent on the forearms, lower extremities and lower abdomen; a sparse growth was present on the areola of the breasts. The heart was slightly enlarged to the left. A short, soft, blowing, systolic murmur was audible at the apex, and was transmitted to the lower sternum; a similar murmur was heard at the first and second right interspaces. The pulse was 90 per minute, regular and of good quality. A marked diastasis recti and a slight umbilical hernia were present. The liver edge descended 10 cm. below the costal margin in the mid-clavicular line on inspiration. It was smooth, sharp, of increased consistency and moderately tender on pressure. Only slight pretibial pitting edema was noted. The blood pressure was 185 systolic and 95 diastolic. No other physical abnormalities were found at this time. The urine was normal. A two meter film of the heart and aorta revealed a slightly in-

*From the Division of Medicine, Michael Reese Hospital, and from the Department of Medicine, Northwestern University School of Medicine.

Chart 1. Showing the effect of lipocaic upon the function of the liver and upon the blood cholesterol. Note the normal response to the bromsulphalein, hippuric acid and glucose tolerance tests and the rise in blood cholesterol after treatment. (Normal fasting blood sugar according to method employed: 60-95 mg. per 100 cc. blood).

increased cardiothoracic ratio (14.3/27.7 cm.), a normal cardiac outline and a calcific plaque in the aortic arch. Having shown no response to digitalis and rest after a period of four weeks, she was admitted to the Michael Reese Hospital on April 17, 1937, for observation (service of Dr. Sidney Strauss). Her temperature was 98.6 F.; pulse 90 and respirations 18 per minute. Weight 193 pounds (87.8 Kg.). Physical examination elicited the same findings as recorded above. The urine was negative except for a trace of albumin. Blood examination: Hemoglobin, 65 per cent; erythrocytes, 4.1 million; leucocytes, 7600; differential formula, normal. Sugar, 97 mg. per 100 cc. blood (normal, 60-95 mg.); non-protein nitrogen, 38 mg.; cholesterol, 176 mg. Wassermann and Kahn tests, negative. Electrocardiogram: Rate 88. P-R interval 0.16 sec. QRS up in leads 1 and 2, small and slurred in lead 3. S-T, and, are slightly depressed. T is inverted in leads 1 and 2, and inverted and small in lead 3. QRS mainly up. Sinus rhythm.

Tentative diagnosis: 1. Obesity. 2. Hypertension. 3. Arteriosclerotic heart disease with slight cardiac hypertrophy; arteriosclerosis of the aorta. Sinus rhythm. 4. Secondary hypochromic anemia. 5. Exclude ovarian, adrenal and pituitary disease as the cause of the hirsutism.

The therapy consisted of bed rest, digitalis and an 800 calorie diet. On the third day of admission, her pulse rate was 80 per minute. The visual fields were normal. Roentgenograms of the sella turcica were normal. A fasting blood sugar of 190 mg. was obtained on the fifth day. May 3, a glucose tolerance test,* injecting 50 cc. of 50 per cent glucose intravenously, yielded the following results: Fasting control, 158 mg.; after 15 minutes, 303 mg.; 1 1/2 hours, 202 mg.; 2 hours, 181 mg. (Chart 1). On the same day the blood calcium was 10 mg. per 100 cc. blood; phosphorus 1.3 mg. (normal, 2-3 mg.).

Although the weakness was less marked, her general

condition after 2 1/2 weeks had shown little if any improvement despite the fall in blood pressure to 150 systolic and 80 diastolic, a pulse rate of 72 per minute and a loss of 20 pounds (9.1 Kg.) in weight. The liver had not receded in size, and was still tender on pressure and of increased consistency. It seemed apparent at this time, that the disorder of the liver was unrelated to the cardiac state, and that a diagnosis of hepatic cirrhosis was more tenable.

On May 5, the icterus index was 5; van den Bergh test: direct, faint delayed positive; indirect, faint immediate positive. May 7, the hippuric acid test of liver function revealed an excretion of only 49 per cent of normal (1.48 Gm. in terms of benzoic acid).† Pneumoperitoneum disclosed a globular mass, believed to be an arrhenoblastoma of the ovary, located in the right side of the pelvic cavity. For the first time, a glycosuria was detected on this day, the maximum daily excretion prior to operation being 6 Gm. On May 9 the bromsulphalein test revealed 20 per cent retention at the end of 30 minutes (Chart 1). The blood sugar was 173 mg.; weight, 177 pounds (80.5 Kg.).

A laparotomy was performed on May 12 by Dr. M. L. Leventhal, and a slightly enlarged, freely movable, right ovary (fibroma theca cellulare [Dr. O. Saphir]) was removed. The left ovary was shrivelled, small and hard. The liver was enlarged and appeared grossly fatty, yellowish and mottled. The gall bladder was distended and contained a palpable, freely movable gall stone. Upon request, a section of the liver was removed for biopsy and fixed in Zenker's solution.

Histologic examination (Figs. 1 A and B): The architecture of the liver is barely recognizable. Throughout most of the section, the liver cells are swollen and the cytoplasm is clear, filled with large round vacuoles and does not take the stain; the nuclei either do not stain or are displaced to the periphery of the cells, presenting a "signet-ring" appearance. In a few areas, more normal appearing liver cords are seen, the cells of which are

*All glucose tolerance tests were performed by Dr. Rachmiel Levine of the Department of Metabolism.

†Normal, 3.0 Gm. Limits of normal—85-110% excretion (14).

Fig. 1A

Fig. 1B

Fig. 1. Photomicrographs of the liver before treatment, showing marked fatty infiltration and degeneration (fatty metamorphosis). Hematoxylin and eosin stain. A.—X 140. B.—X 300.

swollen, their cytoplasm, faintly eosinophilic, coarsely granular and occasionally vacuolated, and the nuclei, pale, vesicular and centrally placed. The sinusoids are obliterated by the markedly swollen liver cells. In the periportal areas, there are focal accumulations of lymphocytes with occasional polymorphonuclear leucocytes. The central veins are normal. Diagnosis: Marked fatty metamorphosis of the liver.

Post-operatively, the diabetes became worse, the daily sugar excretion increasing to a maximum of 22.8 Gm. on the third day, accompanied by acetoneuria, 1 to 2 plus; and gradually decreasing to normal on May 21. On May 23, convalescence was complicated by a carbuncle of the sacral region, which required prolonged postoperative care. The dietary management consisted of C 150 P 70 F 70 on May 15 to 17; an 800 caloric soft medical diet from May 18 to July 4, and C 100 P 75 F 60 from July 4 to 8. The total insulin requirement was 350 units, administered between May 17 and June 26. She was discharged from the

hospital on July 8, at which time the hepatic findings were unaltered. Her weight was 165 pounds (75 Kg.).

She returned to the Mandel Clinic on July 23 and periodically thereafter. Although a diet of C 100 P 75 F 100 was prescribed, she rarely ate this amount. On August 12, a glucose tolerance test (50 cc. of 50 per cent glucose intravenously) resulted in the following blood sugar values: fasting, 89 mg.; after $\frac{1}{2}$ hour, 151 mg.; $1\frac{1}{2}$ hours, 181 mg.; $2\frac{1}{2}$ hours, 131 mg.; 3 hours, 130 mg. (abnormal). On September 27, the bromsulphalein test again disclosed 20 per cent retention of the dye at the end of 30 minutes. The liver had remained 10 cm. below the costal margin in the mid-clavicular line on inspiration, was moderately tender on pressure and of increased consistency. The urine had been sugar-free since May 21.

Through the generosity of Dr. Lester R. Dragstedt, a supply of "lipocaine" was obtained, and on September 23, a daily dose of 76 grains (5 Gm.) orally was prescribed for the patient. She was observed subsequently at weekly

Fig. 2A

Fig. 2B

Fig. 2. Photomicrographs of the liver after 88 days of lipocaic therapy, showing only slight fatty metamorphosis of the liver. Hematoxylin and eosin stain. A.—X 130. B.—X 300.

intervals. During the first week she seemed "groggy" and tired, and frequently felt "flushed"; these symptoms gradually disappeared. During the examination at the end of the second week, the patient remarked that the liver was "not tender" on pressure. After four weeks of therapy she felt "lots better," i.e. stronger. Although the size and consistency of the liver had shown no change, tenderness could not be elicited on firm, deep pressure. Weight 169½ pounds (77 Kg.). At the end of six weeks, the liver was still of the same size but the edge seemed thinner and less resistant. During the seventh week, there was a marked diarrhoea with 12—15 loose stools daily, lasting for six days. At this time, the edge of the liver was 6 cm. below the costal margin in the mid-clavicular line on inspiration; the consistency was distinctly decreased and the edge definitely thinner. In the subsequent week, the patient regained 2 pounds in weight. The physical findings noted at the preceding examination were confirmed. Nine weeks after therapy was begun, the bromsulphalein test was

repeated, revealing less than 10 per cent retention at the end of 30 minutes. On the following day, December 1, the hippuric acid test showed 108 per cent excretion (3.23 Gm. in terms of benzoic acid) (normal). After ten weeks of therapy the patient felt "fine" and had no complaints. The liver edge was 4 cm. below the costal margin on inspiration, non-tender and of normal consistency. At the next visit (eleventh week), she gave a history of severe sticking pain in the right hypochondrium of 3 days' duration. The liver edge was 1.5 cm. below the costal margin in the mid-clavicular line on inspiration. During the twelfth week, she had another severe biliary colic lasting for one day. Examination revealed no new findings except for a palpable globular mass in the right hypochondrium, extending below the edge of the liver. A diagnosis of cholelithiasis with probable hydrops of the gall bladder was made and surgical intervention advised. Throughout this period of observation, the fasting blood

sugar values ranged from 89—105 mg., and the urine was consistently sugar-free.

She was readmitted to the Michael Reese Hospital on December 21, 1937. Her temperature was 98.6 F, pulse 68 and respirations 18 per minute. Weight 171½ pounds (78 Kg.) The slight pretibial pitting edema, which was again noted, was probably due to a peripheral circulatory disorder. The blood pressure was 156 systolic and 88 diastolic. The urinalysis was negative. Blood examination: erythrocytes, 4.75 million; hemoglobin, 70 per cent; leucocytes, 11900. Sugar, 88 mg.; non-protein nitrogen, 38 mg.; total cholesterol, 348 mg.; cholesterol esters, 154 mg.; icterus index, 10; Van den Bergh, direct, delayed positive; indirect, immediate positive.

On December 24, she was operated upon by Dr. R. B. Bettman. A hydrops of the gall bladder, with a gall stone impacted in the cystic duct and two others lying in the fundus, was found and removed. The liver was remarkably different from its earlier appearance. Whereas it had been yellowish and mottled previously, it was now uniformly reddish brown in color, and normal in size and consistency. A specimen of the liver was again obtained for biopsy and preserved in formalin.

Histologic examination (Figs. 2A and B) reveals a strikingly different picture. The architecture is clearly recognizable now. The liver cords are still swollen. The cytoplasm of the cells is coarsely granular and stains more deeply. Only occasional liver cells are filled with large round vacuoles. The nuclei are pale, vesicular, round or oval and, for the most part, centrally placed, an occasional cell exhibiting an eccentric nucleus. The sinusoids are compressed by the swollen liver cords. In the periportal areas, occasional accumulations of lymphocytes and polymorphonuclear leucocytes are seen; the connective tissue is not increased. The central veins are normal. Diagnosis: Slight fatty metamorphosis of the liver.

Her post-operative course was uneventful, and the urine remained normal throughout. December 31, the fasting blood sugar was 110 mg.; total cholesterol, 288 mg. On January 3, 1938, a glucose tolerance test, injecting 50 cc. of 50 per cent glucose intravenously, revealed the following blood sugar values: fasting, 87 mg.; after ½ hour, 182 mg.; 1½ hours, 108 mg.; 2½ hours, 83 mg.; 3 hours, 59 mg. In the light of Soskin and Mirsky's work (16), this normal tolerance curve may be interpreted as indicating recovery in hepatic function. She was discharged in good condition on January 4, 1938, twelve days after operation. Lipocaic therapy, discontinued during the post-operative period, was resumed on this day.

On February 2, the total blood cholesterol was 354 mg. per cent; cholesterol esters, 156 mg. per cent. She has been observed at bi-weekly intervals and has remained in good condition.

COMMENT

The remarkable recovery in the functional capacity (Chart 1) and in the gross and histologic appearance of the liver, as observed in this instance of fatty metamorphosis following treatment with lipocaic, is of considerable clinical interest. In critically establishing the therapeutic effect of any medication, however, it is requisite that the rôle of the natural course of the disease as well as the incidental effect of all contemporaneous factors be excluded. To fulfill these requirements, our patient was carefully observed for 138 days before instituting lipocaic therapy, and during this period no medication was prescribed. Further, the diet was maintained at a low carbohydrate level in order to obviate the regenerative effect upon the liver known to follow a high carbohydrate intake. Repetition of the liver function and glucose tolerance tests in conjunction with the physical findings indicated a static condition in the liver prior

to treatment with lipocaic. It is clearly evident that the insulin given during the post-operative course, if in any way influential, would have manifested its beneficial effects during the control period. Similarly, the early weight loss can be of no significance, for her weight at the time of the respective biopsies was practically the same.

The photomicrographs of the liver before treatment (Figs. 1A and B) are in all respects identical to those of depancreatized dogs (2, 6, 10, 17), and the second specimen (Figs. 2A and B), obtained after 88 days of lipocaic, is histologically indistinguishable from the appearance of the regenerated liver of dogs following raw pancreas, lecithin, choline or lipocaic therapy (2, 6, 10, 17). Experimentally, more than 16 weeks of pancreatic feeding are necessary to effect a return to the normal fat content (18). Hence, had our second biopsy been made after a longer period of treatment, it seems likely that further histologic improvement would have been manifest.

Another interesting phenomenon not necessarily related to the fat mobilizing principle of lipocaic is the development of hypercholesterolemia following treatment. Although this finding is not in agreement with that of Grayzel and Radwin (12a) in juvenile diabetes, nevertheless, it parallels the observations of Chaikoff and Kaplan (19) on depancreatized dogs receiving raw pancreas. Moreover, the rapid fall in the cholesterol level, noted in dogs when pancreatic feedings were discontinued, was likewise observed in our patient during the post-operative course when lipocaic was withheld, the previous level becoming reestablished after lipocaic was resumed (Chart 1). It has been found (18) that the substance in raw pancreas effective in elevating the blood cholesterol is thermolabile, thus being different from the essential factor in lipocaic and from choline, both of which are thermostable.

The appearance of increased amounts of sugar in the urine, usually observed in dogs during recovery, did not occur in this patient. This finding, however, has also been reported missing in some dogs (5a and 5d). It must be remembered that the increased hyperglycemia and glycosuria following treatment does not represent a primary exacerbation of these symptoms, but merely a return to the state of affairs which existed before the fatty metamorphosis of the liver occurred. Hence the occasional failure of these effects of choline or lipocaic to appear, as in our case, may be due to either of two circumstances: It has been shown that an irritative phase precedes the depression of liver function caused by toxic agents (16). It is therefore possible that our patient had not progressed beyond the irritative phase, and that her carbohydrate tolerance had not yet spontaneously improved prior to lipocaic administration. Under these circumstances, no return to decreased tolerance was to be expected after treatment was begun. This explanation, however, is not in accord with the initially impaired liver function of our patient, as shown by the results of the bromsulphalein, azorubin-S and hippuric acid tests. A more likely explanation of the lack of increased hyperglycemia and glycosuria is based upon the recent observations of Soskin (20), who found that prolonged or repeated fatty metamorphosis of the liver in depancreatized dogs may result in irreversible depression of liver function. In such cases the fat disappears from the liver under the influence of

choline, but gluconeogenesis does not return to its previous vigour. The degree of permanent liver impairment which accompanies the phenomenon may not be detectable by the ordinary liver function tests, but is reflected in the 24-hour blood sugar variation (21).

Finally, whatever may be the mechanism by which the results of lipocaic have been attained, whether by its action as a hormone, or by virtue of its effect upon choline metabolism, or both, its beneficial effects in this patient are clearly defined, and represent the clinical counterpart of the findings observed in experimental animals.

SUMMARY

A proved instance of recovery from fatty metamorphosis of the liver associated with diabetes mellitus following treatment with lipocaic is recorded. Biopsy studies made before and after treatment were correlated with the results of liver function and glucose tolerance tests, cholesterol determinations and with the clinical course. The changes observed represent the clinical counterpart of the findings noted in experimental animals.

DISCUSSION

DR. ALBERT M. SNELL (Rochester, Minnesota) : I was happy to have the opportunity to hear this interesting report by Doctor Rosenberg. It seemed to me this establishes without much question the value of the administration of lipocaic in fatty metamorphosis of the liver associated with diabetes; perhaps in some of the earlier cases reported by Judd, Kepler and their colleagues, the patients would have been benefited had the use of choline been continued for a longer period, or it is quite probable that lipocaic alone would have been of benefit had it been available at the time.

There is one other condition in which lipocaic is of clinical value; namely, in complete destruction or atrophy of the pancreas. At the clinic we have records of one patient who had proved pancreatic lithiasis; a very large fatty liver; ascites; edema; and who retained bromsulphalein. All of the hepatic changes and other symptoms disappeared under treatment with lipocaic, the diabetes persisting about as before. We have had this man under observation for about two years and a recent report indicates that he is well; his liver is not palpable and he is able to work every day.

Doctor Bollman recently has attempted to determine whether lipocaic is a general protective substance against fatty metamorphosis of the liver. His dogs were given alcohol to the point of intoxication twice a day and a diet high in fat and moderately deficient in carbohydrate and protein. The normal fat ratios were reversed by this procedure. One animal, which received 0.5 gm. of lipocaic per kilogram of diet, had almost a normal quantity of liver fat and the concentration of glycogen in the liver was relatively high. Unfortunately, two subsequent animals which were given large doses of lipocaic and the same diet failed to be similarly protected. Doctor Bollman is continuing these experiments and it may be possible for him to show that lipocaic has some protective effect against fatty metamorphosis of the liver.

DR. EARNEST H. GAITHER (Baltimore, Md.) : Dr. Rosenberg asked me some time ago to discuss this paper.

I am sure we all feel a deep sense of gratitude to Dr. Rosenberg for his excellent and enlightening presentation of this most important subject.

The work is quite new, and we shall anticipate the results of further research; these, I feel, will tend definitely to prove the claims made by those workers who have developed this new theory based upon what at this moment seem quite solid and convincing facts, i.e., those studies by Dragstedt, Prohaska and Harms, who prepared a fat free alcoholic extract of beef pancreas ("lipocaic") which, when fed to depancreatized dogs, proved as effective orally as either raw pancreas, lecithin, or choline, in preventing or curing fatty metamorphosis of the liver; they believe this to be a "fat metabolizing hormone", concerned in the normal transport and utilization of fat.

It was indeed a stroke of good fortune that Dr. Rosenberg had the opportunity of administering lipocaic to a patient with marked fatty metamorphosis of the liver associated with diabetes mellitus, thus correlating the clinical observations with the results of liver function and glucose tolerance tests, and with the gross and histologic appearance of the liver both before and after treatment. Dr. Rosenberg has most convincingly presented the striking results.

This new method of attacking fatty metamorphosis of the liver associated with diabetes mellitus, seems at this time to be an outstanding achievement, and we shall hope that other workers will carry on researches in this

domain in order to provide a large group which will definitely prove the claims and values of this method, which seems to possess true merit.

DR. DAVID H. ROSENBERG (Chicago, Ill.): I have nothing further to add except to thank the discussants for their generous and interesting remarks.

The Effect of Therapeutic Agents on the Volume and the Constituents of Bile*

By

CHICAGO, ILLINOIS

A REVIEW of the literature reveals many controversial points regarding the factors concerned in bile secretion and bile salt metabolism. Little is known regarding the precursor substances of the bile acid molecule, however, it seems certain that some of the amino acids and vitamins A and D are related to bile acid synthesis (1-7), and that bile acids are formed only by the hepatic epithelium (8-10). Although bile acids and cholesterol or its oxidation products are closely related structurally (11), there is no experimental evidence indicating that the latter are related *in vivo* to bile acid synthesis (12). Protein in the diet increases, while carbohydrate feeding diminishes both volume and bile acid secretion (1, 13-19). The close relationship between bile acid production and urinary nitrogen excretion indicates that bile acid production is intimately related to protein metabolism (21, 22). Fats and soaps are known to influence the flow of bile in the intact animal by their effects on the extrahepatic biliary system, however, the effect of fats on the activity of the hepatic cell is controversial (13, 17, 23-28).

There is considerable difference of opinion regarding the effect of drugs on hepatic secretory activity. This is due in part to the comparison of results obtained by acute experiments on anesthetized animals with those from chronic fistulous dogs, and in part to inadequately controlled experimental procedures with large experimental errors. In order to conserve space, the reported effects on bile flow of some of the more common drugs are tabulated in Table I.

It should be pointed out that in most previous studies on bile secretion conclusions, with few exceptions, have been based on changes in bile volume. It is desirable, at this point, to distinguish between two types of secretory activity, namely, (a) the secretion of water which increases the volume-output of bile without regard for the quantitative amounts of the various constituents, and (b) the secretion or excretion of the individual biliary constituents other than water. Our interests have been directed toward the latter. Before discussing the choleretic (increase in secretory or excretory activity of the liver) properties of the drugs we have studied, it is necessary to consider, briefly, the chemical similarity of the more common bile acids.

THE BILE ACIDS

Only traces of bile acids occur free in bile; essentially all of the bile acids present are paired in peptide-like linkage with the sodium salt of either glycine or taurine. Neither tryptic digestion nor bacterial decomposition in the alimentary tract ruptures this combination (28, 29), thus, bile acids are absorbed from the intestine in their original conjugated form. The glycine and taurine portion of the bile salt molecule is the same in all animals, but the cholic acid part of the molecule differs slightly in some animals. This difference is confined solely to the number and position of the hydroxy groups present.

The determination of the structure of the bile acids has been an arduous task requiring almost a century for its solution, and the awarding of the Nobel prize in 1928 to Wieland and Windaus was a fitting tribute to the brilliant success of these investigators. All of the known bile acids have been submitted to dehydration followed by hydrogenation to be converted into the OH-free parent compound, CHOLANIC acid. Cholic acid is the most common bile acid; its molecule contains three OH groups in positions 3, 7 and 12 (3-7-12 trioxycholanic acid). Desoxycholic acid occurs in the bile of some species in several isomeric forms; its molecule contains two OH groups. The desoxycholic acid of ox-bile and anthropodesoxycholic of human bile are the same substance (3-12 dioxycholanic acid). Isomers of this bile acid have been isolated from goose bile, chenodesoxycholic (3-7 dioxycholanic) acid, and from hog bile, hyodesoxycholic (3-6 dioxycholanic) acid. Lithocholic acid contains one OH group (3-oxycholanic acid); it was first isolated from gall stones and is found in significant amounts only in herbivorous bile.

Another bile acid complex, occurring naturally in bile in traces, but which does not concern the present considerations, is CHOLEIC acid; this is a stable combination of three or more molecules of 3-12 dioxycholanic (desoxycholic) acid in molecular combination with fatty acid.

Aside from the bile acids occurring naturally in bile, there are commercial preparations in which the hydroxy groups have been oxidized to the keto-forms. These constitute the "dehydrocholic" acids; they are probably better known under the trade names "Decholin" and "Ketochole." Such preparations are mixtures of mono-, di-, and tri-ketocholanic acids. "Decholin" is practically pure 3, 7, 12 triketocholanic acid.

TABLE I
Effect of drugs on bile flow

Drug	Effect on Bile Flow	Observers
Aliphatic compounds:		
Chloral and chloralose	Increased	Chabrol (1930)
Avertin	Doubled	Chabrol (1930)
Ethyl alcohol	No effect	Chabrol (1930)
Ethyl alcohol	Increased with 200 cc. 10%	Okada (1915)
Ethyl alcohol	Decreased	Winogradow (1927), Propkop 1928
Aromatic compounds:		
Salicylic acid	Increased	Doyon and Dufourt (1897), Winogradow (1908), Okada (1915), Specht (1923), Chabrol (1929)
Salicylic acid	No effect	Smyth and Whipple (1924)
Acetyl-salicylate	Increased	Winogradow (1924), Chabrol (1929)
Phenyl-salicylate	Increased	Meissner (1926), Chabrol (1929)
Salicyl-salicylate	Increased	Chabrol (1929), Kaufheil and Rappoport (1932)
Benzoate	Increased	Gumprecht (1895), Klonka (1905), Meissner (1926), Robson (1890), Paton and Balfour (1891)
Phenol, catechol, hydroquinone, Pyrogallol, naphthol, resorcinol, guaiacol, vanillin	Increased	Chabrol (1929) (1931)
Cinephen	Increased	Horsters (1925), Adler (1926), Spurling and Hartman (1926), Meissner (1926), Chabrol (1929), Franke (1930)
Cinephen, purified	Increased	Bradley (1938)
Phenolphthalin	No effect	Tunnicliffe (1902)
Phenolphthalin	Increased	Fleig (1908)
Tetraiodophenolphthalin	No effect	Chabrol (1929)
Calomel	Increased	Pitini and Fernandez (1914)
	Decreased	Doyon and Dufourt (1897), Paton and Balfour (1891)
	No effect	Okada (1915), Stransky (1925), Adler (1926), Smyth and Whipple (1924)
Morphine	Decreased	Picard (1879), Paval et al (1929)

EXPERIMENTAL

The many variables inherent in experimental methods previously available for collection of bile from chronic bile fistula animals is well known to all who are familiar with bile-fistula dogs. For the past two years we have employed an improved method which permits quantitative study of the secretory activity of the liver. The continuous application of a slight negative pressure to the tubing draining the biliary passages has eliminated many of the variables and has furnished quantitative data which reveal that the liver is as constant in its secretory activity as the other externally secreting glands (30, 31). Within the past decade dependable chemical procedures have been developed for the quantitation of biliary constituents. In view of the increasing interest in the chemical composition of bile, it has become desirable to study the effect of certain therapeutic agents on bile secretion, employing these improved physiological and chemical methods (for details see reference 31).

High Fat Diet: Since the lipid fraction of bile is known to aid bile salts in keeping cholesterol in solution, we desired to know if the lipid fraction of bile could be influenced by dietary means. *Purified linseed oil* was selected because it contains considerable unsaturated, diffusible fatty acid which can be absorbed in the absence of bile (33). Two cc. per kilo was fed daily with the regular diet, the latter being reduced sufficiently to cause the daily caloric intake to remain unchanged. (Fat in diet increased from 39 to 60 per cent of the total caloric intake). Over a three day period volume output was increased by an average of 16 per cent, basal bile acid output was unchanged, and cholesterol and biliary lipid output were each increased by an average of 37 per cent.

Commercial bile acid preparations: It is generally agreed that bile salts and their derivatives are the most effective stimulants of bile flow, and experimental or substitutional bile salt therapy in biliary disease is becoming a common clinical practice. As a result, a number of commercial bile salt preparations are available; among the better known of these are Decholin (Riedel-de Haen), Ketochol (Searle) and Bilron (Lilly). Dechacid (Wilson Lab.) is a newer product as yet not on the market. These preparations represent three different types of bile acid derivatives (vide infra).

The comparative effect of the above bile acid derivatives was determined on a number of bile fistula dogs. The data is summarized in Table II (for individual analyses see reference 31). Briefly, the procedure for testing the effects of drugs on biliary constituents was based on the following procedure. During the first three days of a consecutive six day period the animals were maintained on a standard routine without the return of bile. The output of biliary constituents during this period represented control or "basal" output. During the remaining three days the drug to be tested was administered in divided doses following meals. Comparison of the values for this period were made with those of the control period.

Bilron proved to be a potent choleric. This preparation contains the acid-insoluble iron salts of the natural conjugated bile acids of ox-bile. Five grams daily increased volume output by 57 to 116 per cent; cholates were increased by 68 to 234 per cent; cholesterol by 69 to 350 per cent; pigment by as much as 65

per cent, and fatty acids by 59 to 129 per cent. The increased bile acid output resulted from the presence in the bile of cholates administered in this bile acid preparation.

Dechacid contains the *conjugated* bile acids of ox-bile which have been oxidized to the keto- form (conjugated ketocholelanic acids). This preparation was also choleric when administered in daily doses of 3.6 and 5 grams. Volume output was increased by 36 to 79 per cent. Cholate excretion was unchanged (the oxidized derivatives contain no cholates, thus their presence would not be detected by the method used for analysis) but the total bile acid output was increased due to the presence in the bile of the administered keto-cholelanic acids. (Keto-cholelanic acids were determined by a method devised at the Wilson Laboratories, Chicago) Cholesterol output was increased by 30 to 110 per cent while pigment output was not materially altered.

Decholin and *Ketochol* contain the oxidized, unconjugated bile acids of ex-bile (unconjugated ketocholelanic acids), thus, they differ from *Dechacid* only by the fact that they are unconjugated. Five grams daily increased volume output by as much as 190 per cent. Cholesterol output was increased by 10 to 125 per cent with *Ketochol*, and decreased by 28 to 56 per cent with *Decholin*. Fatty acid elimination was increased comparably with all of the bile acid preparations (by 14 to 129 per cent). However, the oxidized, unconjugated preparations depressed bile acid synthesis, as reflected by cholate output, by 12 to 50 per cent. This latter finding has been observed by others (32). Due to the presence in the bile of keto-cholelanic acids, total bile acid output (cholated plus ketocholelanic acids) approximated the cholate output during the control period. Since the *conjugated* ketocholelanic preparation (*Dechacid*) did not suppress cholate synthesis in a similar manner one of two conclusions seems likely. Either the suppressed cholate output occurred as a manifestation of toxicity of "free" ketocholelanic acid on the

hepatic cells, or the synthetic activity of the hepatic epithelium was diverted to the function of conjugating the unconjugated oxidized bile acid molecules.

ASPIRIN, in doses of fifteen or twenty grains daily, increased volume output by 3 to 98 per cent, however, total cholate excretion was reduced by 10 to 35 per cent in four of six dogs. Cholesterol output was not affected consistently, and pigment output was increased insignificantly in three of six dogs. It was found that salicylic acid was present in the bile in concentrations of 12 to 20 milligrams per cent; over eighty per cent appeared in the bile in conjugated form.

SULPHANILAMIDE was tested to determine if dosages comparable to those used clinically would produce toxic manifestations in the liver (decreased bile acid synthesis) and to estimate the concentration of sulphanilamide in bile following its oral administration such dosages. Administered orally in doses of ten and twenty grains (one to two grains per kilo), sulphanilamide produced no significant changes in bile secretion or in the biliary constituents. Likewise, ten grains daily had no influence on the choleric action of ox-bile salts. Analysis of the bile in these experiments showed sulphanilamide to be present in concentrations of four to eleven milligrams per cent, amounts which have been reported to be bacteriostatic for certain organisms.

CALOMEL and **AMMONIUM CHLORIDE** were tested because of the clinical impression that these drugs are of value in promoting bile flow and in inducing clinical improvement in cases of "torpid" livers. Calomel in particular has long enjoyed the reputation of being a stimulant to bile flow. When administered in daily doses of 100 and 200 milligrams, the volume of bile flow was increased in only one of five dogs and decreased insignificantly in three dogs. Cholate excretion and cholesterol output were not altered significantly; pigment output was increased 39, 71, and 74 per cent in three dogs and not materially

altered in two. From this data it seems doubtful that calomel is of any value as a cholagogue.

AMMONIUM CHLORIDE, in doses of 15 grains daily, produced a questionably slight increased flow in three of five dogs and increased cholate output even less definitely. Cholesterol output was decreased by 17 to 54 per cent in all experiments, and pigment was increased insignificantly in three instances.

Since the usual trend of cholate output was less with many drugs studied than that observed with ammonium chloride, we desired to rule out the possibility that the amino groups from this compound might contribute to bile acid synthesis. Furthermore, since urea is known to be a strong diuretic we desired to learn if it might also increase bile flow. When urea was administered orally to three dogs in doses of 5 grams daily, it appeared entirely inert so far as bile secretion was concerned. Thus, any changes in the constituents of bile as a result of ammonium chloride therapy were probably due to the relative acidosis that this drug must have induced in the dosages used.

CALCIUM GLUCONATE was tested because of the relationship of bile to calcium absorption and because this drug is frequently administered in hepatic disease. Given without bile this drug appeared to have no significant effect on bile output or the biliary constituents. Administered with ox-bile salts in doses that are known to elevate serum calcium, calcium gluconate increased the elimination of biliary constituents significantly in only one of four dogs.

Mucin and Chondroitin were tested because these drugs are of reputed clinical benefit in conditions which may be possibly associated with disturbed hepatic function (i. e. peptic ulcer, migraine, and also in Eck fistula dogs). Both drugs were without effect on bile secretion or the biliary constituents in bile fistula dogs.

DISCUSSION

Our data on bile secretion, which has been obtained by a quantitative method in rigidly controlled experiments, indicates that a diet high in unsaturated fatty acids (linseed oil) produces a moderate choleresis and that, except for dog bile, the conjugated bile acids of ox-bile (Bilron and Dechacid) are the most satisfactory agents for inducing choleresis in the dog. Such preparations are true cholericics, i. e. they produce increased flow of bile and increased elimination of biliary constituents. Oxidized, *unconjugated* bile acid hydrocholericics preparations (Ketochol and Decholin) act as hydrocholericics, i. e., they increase chiefly the aqueous fraction of bile. The benzene derivatives, especially salicylic acid, also fall in the latter category.

It seems significant that the oxidized unconjugated bile acid preparations cause an absolute decrease in natural bile acid synthesis. Is this a manifestation of toxic effects on the hepatic epithelium? Certain hepatotoxins, for example small doses of chloroform or phosphorus and some cinchophen preparations, act similarly. It is evident, in the case of the unconjugated ketocholanic preparations, that the suppression of basal bile acid output cannot be attributed to the ketogroups in these oxidized bile acid molecules. If this were the case the conjugated, oxidized preparation (Dechacid) would likewise have decreased natural bile acid output. Ketochol and Decholin differ from the latter only in that they are unconjugated, therefore, the question of conjugation must be pertinent. Though

administered ketocholanic preparations are eliminated in part as such in the bile, the diminished cholate output is not the result of a simple substitution of ketocholanic acid for cholic acid. As much ketocholanic acid appeared in the bile when the conjugated form (Dechacid) was fed as with the unconjugated form (Decholin); yet the basal bile acid output was unchanged with the former and reduced by as much as 50 per cent by the latter. Ketochol, which also depressed cholate synthesis, was accompanied by a considerable increase in ketocholanic acid elimination, which increase augmented the total bile acid elimination to that obtained with conjugated ox-bile salts. Our work indicates that a number of factors must be considered in the selection of a bile salt for therapeutic purposes, e. g., its systemic toxicity when used intravenously, its effect on the liver when given orally for long periods, its effect on the natural composition of bile, its hydrocholeric effect, etc.

Although the benzene derivatives tend to augment bile volume output there seems little indication for the clinical use of such preparations to stimulate bile flow when effective cholericics such as conjugated bile acid preparations are available. The reputed cholagog effect of calomel appears unwarranted from our data, although it does occasionally augment bile volume output slightly. Sulphanilamide, in ordinary doses has no depressing effect on hepatic secretory activity, nor does it interfere with the choleric properties of ox-bile salts. It is eliminated in the bile in concentrations that may make its use in biliary tract infections and in typhoid carriers a rational practice. Studies on this problem are now in progress.

SUMMARY

Using improved physiological and chemical methods, we have investigated the effects on bile secretion of a high fat diet, of bile salt preparations, and of certain drugs used clinically. Three of four commercial bile acid preparations tested increased the output of cholesterol and biliary lipids; linseed oil in the diet likewise increased the output of these constituents as well as the volume of bile.

The *conjugated* bile acid preparations (Bilron and Dechacid) proved superior as stimulants to the flow of bile containing increased amounts of biliary constituents. The oxidized, *unconjugated* preparations (Decholin and Ketochol) increased the aqueous fraction of bile but resulted in an absolute decrease in natural bile acid output.

Salicylic acid increased bile volume output; calomel, ammonium chloride, urea, calcium gluconate, mucin and chondroitin were without significant effect on bile secretion or its constituents.

Sulphanilamide, administered orally in doses of one and two grains per kilo, had no effect on hepatic secretory function and did not interfere with the choleric properties of ox-bile salts. This drug was eliminated in the bile in concentrations that have been reported to be bacteriostatic for certain organisms.

A Modern Conception of Gastric Secretory Functions

Based Upon Recent Investigations and Newer Interpretations

By

SAMUEL MORRISON, M.D.*

BALTIMORE, MARYLAND

WHEN Oliver Wendell Holmes delivered his lecture on "The Contagiousness of Puerperal Fever" he actually presented a theory supported by arguments based upon his own clinical observations as well as upon older material newly interpreted. Though much more scientific in his approach, Semmelweis could not have been more persistent than Holmes in impressing upon others his conviction with regard to the contagiousness of puerperal fever. It must be clear to most of us that contributions to medical knowledge often come piece-meal; all the data may not fit into a harmonious whole but the incomplete story often becomes a probable theory. I hope to make such a contribution.

When the relationship of the stomach and pernicious anemia was discovered, a new field for the study of the gastro-intestinal tract was thrown open. Soon it became evident to some of us that entirely different interpretations could be placed upon older researches and that there existed in the gastro-intestinal tract not only an hematopoietic function but also an intimate motor and sensory overlapping as for example in the poorly understood phases of gastric secretion, which had not yet even begun to be explored.

Without a complete understanding of the normal functions of the gastric mucosa it is hardly possible to interpret pathological changes satisfactorily. So much of the physiology of the gastric mucosa is beyond our ken that successful therapy can hardly be applied when pathologic change takes place. Now we know that there is an hematopoietic function in the cells of the gastric mucosa and we are constrained to ask whether there are also other functions?

GASTRIC ACHYLIA

To begin then we would like to consider the subject of gastric achylia. During the past 5 years we have been led to conclude that gastric achylia is usually relative rather than absolute, false than true, partial than complete, functional than organic. It has been the experience of most of us that with the introduction and utilization of the fractional test meals and hista-

mine many achylia proved to be more apparent than real. Further observations disclosed that the gastric achylia associated with pernicious anemia was a definite persistent achylia. The question arose as to whether the mechanism by which this achylia resulted was different from that associated with certain cases of gastric malignancy or gastritis. Studies of this type at first led to the conclusion that the difference was one of degree, not of kind, but it was difficult to explain why pernicious anemia so rarely followed in long-standing cases of gastritis, even to the degree of atrophy, or was so infrequently associated with gastric malignancy. It appeared that either pernicious anemia was a more general disease than could be accounted for by a gastric locus alone or that it came about only as the result of a combination of gastric changes which occurred very infrequently in instances of gastric achylia due to causes other than pernicious anemia.

INTRODUCTION TO NEUTRAL RED STUDIES

In our clinic we have been able to observe and compare the reaction to numerous test meals with and without histamine. We had adopted the usual criterion for true gastric achylia, that is, failure of response to histamine. In the past 5 years we have become interested in the ability of the gastric mucosa to excrete neutral red. These studies were at first confined to animals and later included humans. However, before analyzing the results it seems essential to remark how few observers realized the inherent possibilities of neutral red as a method of testing the viability of gastric mucosal cells. The literature is too abundant to summarize in this presentation but it is necessary to recall certain key studies which could be profitably reinterpreted today. For example, a careful review of many of the earlier contributions stress the almost unbelievable fact that neutral red is specifically excreted by the oxyntic cell. There are dissenting observations but the consensus of opinion and the better controlled experiments link together, almost inseparably, neutral red excretion with the oxyntic cell. The importance of this observation is highly significant because it immediately introduces us to a possible method of separating the stomach into various parts for study. In other

*Assistant Professor of Gastro-Enterology, University of Maryland, School of Medicine.
Read by Title before The American Gastro-Enterological Association, Atlantic City, Tuesday, May 3, 1938.

words, neutral red has segregated one cell for us and it has accomplished it far more usefully and exclusively than histamine or acid secretory studies in response to test meals because, as has been and will be pointed out, it is able to detect more minute functional capacities of this cell than these other methods.

We, as well as others (1), have observed that pyloric resection influenced and sometimes inhibited fundus excretion of neutral red. Two possible explanations were offered, one that a disturbance of the magenstrasse caused an interruption of reflex stimuli which existed between the fundus and pylorus or second, that there was a hormonal basis, the hormone having its origin in the pylorus. Klein (2) has called attention to the achlorhydria following partial gastrectomy. This achlorhydria is due not to a loss of acid cells, as they are situated in the body and in the fundus of the stomach, but to a loss of the antrum, through which the chemical stimuli of the food (secretagogues) act. However, a small dose of histamine which acts directly on the glandular cells stimulates a normal secretion of hydrochloric acid. In other words, partial gastrectomy does not destroy the ability of the stomach to produce free acid but only interrupts the natural train of events for the secondary phase of the secretion of hydrochloric acid.

The implication of all this work, in addition to the observations based on reliable investigations that pernicious anemia stomachs do not excrete the dye, is far-reaching. Neutral red becomes not only a test for true achylia but also a method by which degrees of impairment of oxyntic cell function may be determined and perhaps also a method of reinvestigating the existence of a possible pyloric hormone. The mere fact that the neutral red excretory test seems to represent the last stage of mucosal activity before complete cessation of oxyntic glandular functions is sufficient to make it replete with possibilities for studying gastric mucosal functions. The test is definitely independent of psychic influence as was pointed out by Henning and Jurgens (3) in a series of 161 cases. Three of their cases demonstrated no secretion of free acid after histamine but a rapid excretion of neutral red.

NEUTRAL RED OUR HYPOTHESIS

A careful consideration of neutral red studies added to our own investigations made it rather clear that neutral red will detect more minutely than perhaps any other test including histamine whether the gastric mucous membrane has latent secretory and excretory possibilities. Furthermore, and because of its selective elimination, it discloses direct information concerning oxyntic cell activity.

THE CLINICAL DATA

Henning and Bach (4) in an interesting discussion, concluded that clinically only the second phase of gastric secretion is studied; this held true for the alcohol-test breakfast, the caffeine test breakfast, as well as Ewald's test meal. Therefore, it is obvious, they maintained that only a partial examination of gastric function is obtained and that no conclusions regarding the physiologic course of gastric secretion instituted by the psychic phase could be drawn. They introduced a method of studying both psychic and chemical phases of secretion and were able to evaluate the function of the individual parts of the stomach. According to their modern conception of the mechanism of secretion the chemical phase of the secretion is related to the function of the mucosa of the pylorus; a direct influence by chemical stimuli of the glands of the fundus presumably does not take place. The first peak of the physiologic activity curve is no doubt conditioned by the parenchyma of the fundus, stimulated by the vagus. This part of the curve tells nothing, therefore, about the functional condition of the glands of the antrum. The second rise of the acidity curve is due to the influence of the secretin on the glands of the fundus. This chemical part of the acidity curve is based, therefore, on the function of both parenchyma segments of the antrum as well as the fundus. From the behavior of these two segments of the acid secretion conclusions may be reached regarding the function of the mucosa of the fundus as well as of the antrum, a possibility which may be considered as a refinement of our diagnostic methods dealing with the gastro-intestinal tract. It could be expected that by the aid of this method isolated functional disturbances of segments of the mucosa could be detected. Psychic inhibitions of the gastric secretion appeared at first during the first phase. This functional disturbance may be designated as functional achylia of the fundus. The isolated achylia of the antrum is characterized by the absence of the second phase and in the presence of a psychic phase in the combined acidity curve. The isolated antrum achylia is observed only in organic diseases.

In a study (30 cases up to the present) which we are now carrying out we have been able to corroborate the greater part of these observations. We have also correlated the excretion of neutral red with these phases. In most instances we found a direct relationship between degree of acid secretion and rapidity of appearance of neutral red. This was especially marked in normal stomachs and in secondary gastric disorders. In all cases of pernicious anemia examined neither a psychic nor an organic phase could be demonstrated

Malignant Neutropenia						Ewald Test Meal	Chemical Phase

Psychic Stimulation												

nor did neutral red appear. In a case of malignant neutropenia there was an achylia during the psychic phase as well as during the 2nd phase. However, neutral red did appear in the 2nd phase in the 90 and 115 minute specimens. We believe this signifies an incomplete atrophy or lack of function of gastric mucosa which probably would return to function if the primary disease could be improved.

Interestingly enough, some of the asymptomatic gastric achylas were found to excrete neutral red and we were stimulated to inquire whether the excretion of neutral red could be interpreted in terms of sufficient gastric function to prevent symptoms. Our data are not sufficient at present to allow us to form any definite conclusions. We have also had cases of apparent achylia gastrica (0-10) in which neutral red was excreted. Later these cases were found to have free acid and a high total acidity. We believe the excretion of neutral red indicated a possible return of function. All of us have had the experience of ulcer symptoms in the presence of an achylia and actual ulcers have been reported. Though the observation is debatable it has been our experience that these patients are aided by alkalies and are sensitive to acid. It would seem that though apparently achylic they may later be capable of secreting their own acid. We have also had patients who demonstrated no secretion of HCl in the fasting analysis or after an Ewald test-meal but did excrete neutral red. Later a fractional meal showed normal gastric acidity. The symptoms of such patients were usually exaggerated by acid-pepsin medication.

The method of performing the combined gastric function test is very simple but is omitted here to conserve space. We used a 1% solution of neutral red (ph. 5.5) autoclaved at 15 lbs. for 20 minutes. From the point of view of stability we also used a 1% solution of neutral red the pH of which was adjusted to 3.5 by the addition of normal hydrochloric acid. This was also autoclaved at 15 lbs. for 20 minutes. Both were tested bacteriologically before use. We also used the dye prepared freshly in water. However, the studies leading to the preparation of the dye are quite detailed and will be reported in another communication.

From these clinical observations, it seems to us that neutral red will aid in diagnosing both functional and organic achylas of the fundus since its excretion depends only on the integrity of the oxyntic cells.

EXPERIMENTAL DATA

The elimination of dye stuffs by the gastric mucosa in various pathological conditions of the stomach and the study of this elimination experimentally in animals have received rather extensive recognition. However, the clinical application of this data and especially that of neutral red, has been rather sporadic and incomplete. In order to furnish a working basis for our investigations it seemed essential to repeat the study of dye elimination through the gastric mucosa (5). At present we are concerned with neutral red which we have been able to demonstrate in the oxyntic cell by a method (6) heretofore not used as far as we have been able to learn. This is an important contribution since the difficulty connected with the study of vital dyes is that they cannot easily be fixed in situ. It would require too much time and space to review the many procedures which we carried out before we were

finally able to develop a successful fixation method and needless to say, we were at times skeptical of our supposition that neutral red which apparently finds many tissues of the body permeable could manifest selective elimination through the gastric mucosa. There can be no question, however, regarding the conclusion we have reached that the parietal cells are the cells chiefly concerned in the elimination of neutral red by the gastric mucosa. Moreover, Kobayashi (7) was able to show that when the parietal cells secrete HCl in a high concentration, they secrete dyestuffs in a relatively large quantity; there was a parallelism between the two which was not true of pepsin. Henning, (8) too, by direct microscopic study concluded that dyestuff excretion is a function of the fundus glands, and that the antrum glands do not participate in this function. There are, of course, dissenting views but in our work (6) we were actually able to fix the neutral red in the parietal cells, something which had not been hitherto accomplished. The stain was definitely confined to the oxyntic or parietal or acid-secreting cells.

Following a routine study of smaller laboratory animals, we decided upon the white rat as an unusually favorable animal for this work, (6), since the observation was made that the fundus was definitely demarcated after the injection of neutral red. The stomach, too, was small enough for fixation in its entirety.

Since the stomach is normally acid in reaction, it was decided to bring an aqueous or saline solution of neutral red in contact with hydrochloric acid and then to add various other agents. When a precipitate formed, that combination was considered a possible means of fixing neutral red in the gastric wall for most of the agents were really fixing agents. Every procedure singly and in combination used in carrying a section through to its resting place on a slide was tried without success until we chanced upon the report of Pfuhr who obtained excellent results with the "Susa" mixture of Heidenhain in retaining trypan blue. We decided to attempt its application to neutral red. Accordingly, the whole stomachs of rats (starved for twenty-four hours) were fixed, after the injection of 1 cc. intravenously of 1% aqueous neutral red, in the "Susa" mixture (corrosive sublimate 4.5 gm., sodium chloride 0.5 gm.; distilled water 80 cc. to which was added immediately before use—trichloroacetic acid 2.0 gm., acetic acid 4 cc. and formol 20 cc.). They were then transferred from the fixative directly to 90 per cent alcohol and during the course of the same day through absolute alcohol. (These steps are mentioned because in previous experiments the neutral red granules were dissolved out by various agents used in the fixing process. Water and the dilute alcohols were especially likely to wash out the dye). The stomachs were then carefully cut through longitudinally and passed into carbon disulphide (not previously used), and then into a mixture of equal parts of carbon disulphide and soft paraffin. After 8 to 12 hours in soft paraffin the halves were embedded in hard paraffin. Complete serial sections were made at 5 to 7 microns, alternate sections being stained with phloxine-methylene blue as a control on localization of the parietal cells. The experimental sections of neutral red were carried through the alcohols, cleared, and mounted in neutral balsam. Examination of these sections showed that it was possible to retain the

neutral red dye, not as a pure red but as yellowish red, which could readily be detected in the canaliculi of the parietal cells. The localization of the neutral red granules corresponds exactly with the anatomic distribution of parietal cells in the phloxine-methylene blue preparations. The same results were obtained in dogs.

Therefore, by the use of the "Susa" mixture of Heidenhain, neutral red granules were found to be selectively eliminated by the parietal cells of the white rat's and dog's stomachs. Since the oxyntic cell secretes hydrochloric acid and excretes neutral red and since both of these functions are absent in true achylia gastrica it becomes clear that these two tests represent the most important method by which a diagnosis of true achylia gastrica may be reached. Moreover, since the cessation of hydrochloric acid occurs long before the failure to excrete neutral red, as we have been able to demonstrate in animals and humans, it would appear that the HCL secretion function of the parietal cell is more sensitive to obnoxious agents than the neutral red excretory function but since many of the achylia excreting neutral red can be shown to be false the conclusion that neutral red excretion is a better test of minimal degrees of parietal cell viability demands expression. Hurst has also directed attention to the observation that the oxyntic are most delicate cells. To this extent, therefore, the condition of achylia gastrica receives further elucidation.

Furthermore, inasmuch as pernicious anemia remains the most outstanding disease of which true achylia gastrica is a part the question arises as to the importance of the oxyntic cell in that disease (9). It is possible that an understanding of the function of this cell may help to make clear some steps in the mechanism of the production of pernicious anemia. At any rate, as long as neutral red is excreted by the parietal cell there is a possibility that the reaction which interfered with cell function may be reversed or reestablished. Several cases of pernicious anemia have been reported in which apparent cure has resulted. One of the more recent was described by Davidson (10). In his case the stomach regained the power of secreting hydrochloric acid and pepsin and, in all probability, intrinsic factor.

Finally not all dyes are excreted through the same channels. It seems probable that we may look forward to the possibility of determining the secretory ability of various portions of the stomach on the basis of their ability to excrete dyes. Kobayashi's observations are suggestive on this point.

ADDITIONAL DATA

In 1934 when Dodds, Noble and Smith (11) found that the posterior lobe of the pituitary contained a substance capable of inducing a severe lesion of the acid-bearing area of the stomach and when later Dodds and Noble (12) discussed the relation of the pituitary gland to anemia and blood formation and reported the development of a definite severe macrocytic anemia in a certain number of rabbits treated in this manner, it seemed possible that the problem of achylia and pernicious anemia might be placed, at least in part, on an endocrine basis. In interpreting their results Dodds and Noble mentioned the possibility that the control of blood destruction by the reticulo-endothelial system may be vested outside the system itself and may reside in the posterior lobe of

the pituitary gland. Finally, from their observations it seemed justifiable to them to consider the possibility of a hormonal connection between the posterior lobe of the pituitary gland, the stomach, and the blood picture.

With these researches in mind we asked Dr. Dodd's cooperation in an investigation of neutral red excretion of the stomach. The experiments, carried out at our suggestion by Dr. W. C. Cutting, showed definitely that in rabbits both dye and acid secretion are decreased by pituitrin administered intravenously. After the administration of histamine (subcutaneously) and neutral red (intramuscularly) a copious secretion of acid and dye result, only to be practically annulled by pituitrin given at the height of secretion of acid and dye. It was demonstrated that acid and dye ran parallel, another proof that the oxyntic cell is concerned with the secretion of acid and excretion of dye, inasmuch as the pituitrin effect is specifically on the oxyntic cell.

It would appear that these pituitary preparations can produce both an achylia and a macrocytic anemia by their specific effects on the oxyntic cells. In other words, interference with secretion of acid and excretion of dye and the production of a macrocytic anemia are all the outcome of destruction of oxyntic cells. It follows that the oxyntic cell may secrete the intrinsic factor. These results cannot be reconciled with the demonstration of Meulengracht, namely, that the pyloric gland region is the anatomical location of the antianemic principle. Both observations, however, can be reconciled on the basis of our conception which credits the pylorus with the possession of a hormone which acts like secretin and thus activates the oxyntic cell to secrete antianemic factor. In rabbits with oxyntic cell destruction produced by pituitrin the pyloric excitant or hormone is present but the oxyntic cells are unable to react to the stimulus. It does seem worthy of consideration that the potent pyloric powder of Meulengracht acts through the oxyntic cell and not directly upon the hematopoietic system.

Recently Cutting, Dodds, Noble and Williams (13) reported that gastric secretion is markedly altered or abolished by any factor which prevents an adequate increase in blood flow to the stomach. They conclude that their investigations (14) indicate that the posterior lobe of the pituitary gland produces a substance which up to the present has not been dissociated chemically from the vasopressive principle, and which is necessary for maintaining the vascular system in such a state that it is capable of a smooth and regular activity, so that the blood flow to secreting glands such as the stomach may be co-ordinated with the secretion, following the application of an adequate stimulus. They believe their findings demonstrate a new relationship between the posterior lobe of the pituitary, the blood flow, and alimentary secretion; and they suggest an entirely new approach to research on disease in which there is a derangement of the alimentary function. Interestingly enough, Cannon has called attention to an achylia resulting from deficient blood supply incident upon stimulation of the sympathetics which in turn caused a contraction of the splanchnics.

CONCLUSION

As the result, therefore, of a careful consideration

of neutral red studies added to our own investigations it seems rather clear that neutral red will detect more minutely than perhaps any other test including histamine whether the gastric mucous membrane has latent secretory and excretory possibilities. Furthermore, and because of its selective elimination, it discloses direct information concerning oxyntic cell activity.

GASTRIC MUCOSA-HEMATOPOIETIC FUNCTIONS

Few investigators actually realized that the gastric mucosa played so important a role in hematopoiesis until the researches of Castle were so convincingly carried through. These "opened a sesame" which led to many fine contributions and hypotheses. However, there were many cases of pernicious anemia which could not be explained for one reason or another on the principles laid down by Castle and others. Many theories were offered. Among them I called attention (15) to the fact that a Meckel's diverticulum occasionally contains the same cell elements which are present in the stomach and arguing by analogy it seemed perfectly logical to suppose that aberrant gastric tissue may be present in other parts of the body. Such heterotopic tissues are already familiar to us not only in Meckel's diverticulum but also in the esophagus, pancreas and intestine. Before this Association at its meeting in May 1936, I did not consider plausible my suggestion that the gastric factor is perhaps also secreted by aberrant gastric tissue as in Meckel's diverticulum. If this is worth consideration we may argue by analogy that the constant presence of gastric achylia is hardly co-incidental in pernicious anemia. Of course it is possible that because gastric achylia is present gastric digestion is unable to elaborate from food the specific antianemic principle present in liver but it is also possible that the failure of the gastric mucosa to elaborate intrinsic factor is the result of the same process which causes gastric achylia. Moreover, the duodenum and possibly other parts of the digestive system also play an important part in pernicious anemia. In this instance a duodenal achylia may interrupt the elaboration of an antianemic substance. However, we have not been able to demonstrate such an achylia so that it is possible that the failure to elaborate the antianemic factor may simply be due to functional or organic dysfunction of the specific cell concerned in its elaboration. It would seem as Braun (16) concluded, that the hormone which is active in pernicious anemia is produced by both the gastric and duodenal mucous membrane of normal persons. The work of Meulengracht would also lead to the same belief except that his demonstration of the antianemic potency of pyloric gland substance seems hardly capable of explaining many cases of pernicious anemia. Meulengracht and Schiodt (17) found considerable pepsin and rennin activity in the preparations from the fundus and little in those from the cardiac and pyloric portion of the stomach of swine. They concluded that pepsin and rennin are probably secreted by the fundus glands only and they established physiologic and anatomic dissociation between pepsin and the antianemic factor in the stomach. Greenspon's work (18) although not substantiated in its major claims, demonstrated the antagonism of pepsin toward the antianemic factor. But pepsin is secreted for the most part from the oxyntic cells of the stomach and

estimates are given of from 25 to 80 times the secretion of pepsin by fundus cells as compared to pyloric cells. In fact some observers doubt any actual secretion of pepsin from pyloric cells.

Now we come to a major theory which I hesitate to present. It runs thusly. We have independently been able to demonstrate that neutral red is eliminated selectively by the oxyntic cell of the stomach. It has also been shown that its quantitative excretion not infrequently runs parallel to hydrochloric acid secretion and that it is influenced by the pylorus. Since pepsin tends to inactivate or antagonize antianemic factor it would seem to be poor bodily economy to have it secreted by peptic cells; moreover, since failure to secrete hydrochloric acid and excrete neutral red, both concerned with oxyntic cell viability, determine the existence of true achylia and since without true achylia true pernicious anemia can hardly be presumed to exist, is it not logical to inquire into the possible role which the oxyntic cell plays in pernicious anemia? Even though complete gastrectomy may not be followed consistently by pernicious anemia *it has occurred*. Of more importance are three other factors: (1) the difficulty of excluding all oxyntic cell tissue as is shown by the recurrence of acid secretion after gastrectomies of various degrees, (2) the plausibility of the existence of aberrant gastric tissue and thirdly, the time factor, namely, how long does it take to develop pernicious anemia? The latter undoubtedly depends upon the diet and vicarious intestinal digestion as well as the amount of antipernicious anemia factor already stored up.

In other words, we must investigate the gastric mucosal functions from the point of view of specific cell activity. To this end, we set out to perform a group of experiments based on the possible presence of a pyloroduodenal hormone and another group which would test the likelihood of the pepsin-inactivating theory on the antianemic factor. We had in mind two possible hypotheses. The first supposed that if a pyloro-duodenal hormone existed then the effect of pyloric-gland substance as reported by Meulengracht could hardly be directly potent but must act upon some other substance to produce secretion of antianemic factor much as secretin acts. The second supposed that if depepsinized fundus could be shown to have antianemic properties then the oxyntic cell must be reconsidered as a potent source of intrinsic factor.

HORMONE. OUR HYPOTHESIS

Experiments (19) with various pyloric extracts suggest that a pyloric secretion may exist and the conception is offered that a composite pyloroduodenal hormone may participate in the elaboration of intrinsic factor as well as hydrochloric acid. The belief is also expressed that the hormone may contain histamine as one of its constituents but does not depend upon histamine alone for its several functions. An hypothesis worthy of further investigation would credit the pyloroduodenal mucosa with the elaboration of a hormone which stimulates the secretion of an intrinsic factor by the gastric glands which, in turn, acts on food materials to produce substances that prevent pernicious anemia.

THE CLINICAL DATA

As a result of our previous studies the idea suggested itself to us that the pylorus (and duodenum)

may be the possessor of a hormone which forms the activating or releasing stimulus for secretion of the "intrinsic factor of Castle." In the past others have called attention to a pyloric (duodenal?) hormone, gastrin by name, which was thought by some investigators, to be fundamentally important in producing one phase of the gastric secretory cycle. Since these studies appeared before Castle's contributions to the elucidation of the mechanism of pernicious anemia, the proof of the degree of potency of pyloric extracts was judged primarily by the amount of acid their administration stimulated. Even with so definite an indicator the conclusions reached by different groups of investigators were in conflict. It has recently been suggested by us (19) that the gastric hormone (pylorus, duodenum) may be associated with the intrinsic factor. As a preliminary approach to the problem we decided to make pyloric extracts using acid secretion as a numerical measure of their potencies and hoping to correlate acid secretion with intrinsic factor secretion, for it was our conception that a composite pyloro-duodenal hormone which stimulated acid secretion may possibly stimulate antianemic, intrinsic factor, secretion. These increased secretions could be therapeutically tested in swine with macrocytic anemia produced by the method of Rhoads. This is an excellent and tremendous field of research which figuratively begs all of you to enter it.

Many workers are of the opinion that the pyloric hormone is identical with histamine but in reviewing the evidence in favor of and against the existence of a pyloric hormone one is left rather in doubt, not only as to its identity with histamine but also as to its existence. There is no question but that Meulengracht's recent contribution (20) seems to have demonstrated that the pyloric gland region has antianemic potency but it is important to recall the older researches of Lim (21). Lim believed it probable that by adopting different methods of extraction the order of potency of pyloric, cardiac, duodenal, fundic, jejunal and ileal extracts could be so altered as to obtain results similar to those of Popielski who found fundus extracts to be as active as those of the pylorus in stimulating digestive secretions. Consideration of this belief in the light of Greenspon's work as well as in the light of some of our own researches now in progress, suggest a whole new field of gastric physiology. Moreover, on the basis of anatomical structure alone the fact that fundus and pylorus extracts may have equal potency must at least suggest that their mechanisms of activity differ.

Ivy (22) has reported that an acid extract of the pyloric mucosa, when injected hypodermically, stimulates gastric secretion. Crystalline histamine has been isolated from such an extract and Ivy believes that the evidence indicates that it is the sole secretory excitant of such extracts; that is, gastrin and histamine appear to be identical. However, it seems clear to most of us that histamine is not known to be a stimulator of intrinsic factor secretion and it would seem plausible to consider that a gastric hormone which has this property must be something other than histamine or something in combination with histamine.

There is another interpretation of Meulengracht's work which possibly offers a more consistent explanation of the various results obtained, especially in the light of our neutral red experiments. It is possible, for example, that the effect obtained after feeding

pylorus powder is due to the activation of oxyntic cell to secrete its contents which may perhaps include intrinsic factor rather than to the supposed presence of intrinsic factor in the pylorus powder. The absence of excretion of neutral red in pernicious anemia stomachs demonstrates in my opinion, not only a failure of fundus secretory activity but also a failure of the normal activating stimulus supplied by the pylorus. In other words, this is a mechanism which we know already exists in the human organism as demonstrated in the mode of action of pancreatic secretin. If the fundus plays only a secondary role in pernicious anemia it would be difficult to explain the remarkable consistency of achylia as well as the occasional changes observed in the microscopic studies of oxyntic cells. On the other hand, if duodenal, pyloric and cardiac powders are in reality activating substances for fundus gland secretion an explanation is possible of certain cases in which acid secretion and intrinsic factor secretion have been known to return. This explanation includes the probable fact that neither pyloric gland region nor fundic gland region were entirely atrophied. In other words, both were ready to function when properly treated. It seems possible, therefore, that pernicious anemia is not an incurable disease, that it is, moreover, curable if the treatment changes from substitution therapy to a type of therapy the purpose of which is to stimulate pyloric gland activity of the affected individual. Such therapy may include the administration of pyloric gland powder temporarily not only as substitution therapy but also as stimulative to the pyloric gland region which in the meantime must be relieved of any local lesion which interferes with its activity. The outlook is more optimistic than in diabetes because oral treatment is effective and the pyloric gland region is so widespread probably including many aberrant rests which make it altogether likely that proper stimulation will bring enough of them into activity to result in the cure of the disease. It is also not impossible to conceive that the pyloric (including duodenal) hormone or even histamine or some similar preparation is the key to the cure of pernicious anemia. If Meulengracht's work is to be interpreted as it is in his article, then in cases of pernicious anemia the pylorus and duodenum may be expected to show some organic or perhaps some detectable functional impairment of secretion. However, reports of histological studies of the stomachs in cases of pernicious anemia, if reporting any change at all in the stomach, usually stress oxyntic cell changes.

That the appearance of pernicious anemia may not be an irreversible reaction is suggested by a number of observations. Castle (23) has pointed out that the deficiency of the gastric factor is apparently the dominant mechanism in Addisonian pernicious anemia in relapse. He believes it probable, however, that the gastric defect is relative rather than absolute. Goldhamer (24) has demonstrated that the intrinsic factor of Castle is present in pernicious anemia stomachs but in decreased amounts while Castle and Minot (25) suggest that the existence of residual amounts of intrinsic factor probably explains the "spontaneous" remissions sometimes formerly observed, especially under optimal nutritional conditions with high-protein feeding. Castle, Heath and Strauss (26) have demonstrated the recrudescence of gastric factor in one patient after treatment with liver extract. Such was

also apparently the case in the patients observed by Barnett (27). This observation probably explains the response of occasional patients with pernicious anemia to the oral administration of extrinsic factor, especially of autolyzed yeast in large amounts. Castle (23) also calls attention to the demonstration of the recrudescence of intrinsic factor in a patient with pernicious anemia who originally secreted free hydrochloric acid without intrinsic factor in the gastric juice. Strauss and Castle (28) point out that at least in some instances of pernicious anemia of pregnancy the administration of extrinsic factor before delivery may produce no effect upon blood formation. After delivery, however, this material may induce clinical improvement and a reticulocyte response which may then be augmented when normal juice is added. The disappearance of the intrinsic factor of the gastric juice during pregnancy is occasionally paralleled by the disappearance of the hydrochloric acid, which likewise may return after the birth of the child.

Suggestive also is the report of Schiff and Tahl (29) that the oral administration of single doses of desiccated hog's stomach stimulates the secretion of free hydrochloric acid in normal persons and in patients with hypochlorhydria and apparent achlorhydria. The prolonged administration of desiccated hog's stomach in cases of genuine achlorhydria or achylia gastrica may cause the disappearance of symptoms without the return of free hydrochloric acid.

EXPERIMENTAL, DATA

In our work (19) pig's pyloric extract was used on dogs but inasmuch as there are conflicting opinions regarding the presence of the anti-anemic factor in the stomach of a dog the interpretation of some of our findings must be made with care. Nevertheless, Morris and his coworkers (30) have found dog's secretion potent insofar as hematopoietic activity is concerned.

The methods of preparation of our extracts from the pylorus mucosa of the hog's stomach have already been published (19). The extracts were divided into 4 portions as follows: supernatant and precipitated sodium hydroxide portions and supernatant and precipitated hydrochloric acid portions. The original combined alkaline portions were tested pharmacologically and no depressor substances were found whereas the acid portions contained the equivalent of .0004 mg. histamine per 1 cc. Later determinations of other preparations disclosed that NaOH and HCl supernatant contained histamine-like substances whereas NaOH precipitated portion did not contain any depressor substances. Our HCl precipitated portion was not satisfactory; the observations were few and inconclusive. Histamine controls were used throughout these observations. NaOH (S) was found to stimulate gastric acidity. It may be supposed that this is due to its histamine content but on the other hand, the HCl (S) as prepared by us, was impotent. The activity of NaOH (S) developed on standing 10 days. No potency was present before that time even when administration was performed intraperitoneally and intravenously. A trypsin odor developed after 10 days but trypsin controls ruled out any part which it may play.

These experiments have as their object the discovery of a possible active principle in pyloric extracts prepared by the method described. Since gastric acid titrations give quantitative readings, that index was used to detect any potency of the extracts. Thus far,

there is sufficient evidence to stimulate further investigation of the supernatant alkaline extract. This portion of the extract was found to contain histamine-like substances but its activity appeared after a period of delay during which there developed a trypsin odor. This odor was found not to be due to trypsin activity and it could not be due to peptic activity since it developed when the pH was 7.8. It is possible that sufficient enzyme was present to break down a protein and release a hormone and it seems to us that this period of delay allows for the liberation of precisely such an active hormone which may contain histamine but is rather a composite hormone capable of stimulating not only acid and pepsin but possibly also intrinsic factor. Fouts, Helmer and Zervas (31) believed that during their procedure of concentration by vacuum distillation, a hormone was released or activated.

This data does not refute the assumption that there may possibly be a pyloric hormone which operates as does pancreatic secretin. Pyloric gland therapy may simply be replacement therapy but it may, after its absorption, also stimulate oxyntic cells to secrete intrinsic factor. Furthermore, it is worth considering whether the oxyntic cell is capable of two types of secretion, one an acid secretion which is external in nature, the other an intrinsic factor which may be primarily an internal secretion although it obviously also appears in the gastric juice.

The author realizes that this part of the work is inconclusive at its present stage of development but it at least suggests an approach to the demonstration of a pyloro-duodenal hormone. All previous researches on gastric hormones should be repeated and re-interpreted on the basis of the newly discovered hematopoietic functions of the gastro-duodenal region. We suggest that a pyloroduodenal hormone could have the same "double play" characteristics of the pancreatic hormone, secretin, which is formed by the epithelial cells of the duodenum under the stimulus of acid contents from the stomach, and only then is available to excite pancreatic secretions. Similarly, who knows but that the pyloroduodenal hormone may stimulate the oxyntic cells to secrete the intrinsic factor (also, but perhaps incorrectly, called addisin). We do not believe a pyloroduodenal hormone could be the intrinsic factor for in that case too, many inexplicable problems would arise, but if it were the "sine qua non" necessary for the production of intrinsic factor by the oxyntic cells then a possible logical theory presents itself. If we could conclusively and consistently demonstrate a potent pyloric extract it would remain (1) to determine how closely this is related to histamine, (2) to correlate the gastric secretion it produces with intrinsic factor secretion, and (3) if results warranted it to determine the therapeutic effect of the pyloroduodenal hormone in increasing intrinsic factor secretion in swine with a pernicious anemia syndrome produced by dietary deficiency.

ADDITIONAL DATA

Granting, as all of us will, that pepsin only partly inactivates intrinsic factor it immediately is apparent that the gastric function would be very uneconomical if intrinsic factor were produced in peptic cells. It would seem that either intrinsic factor is produced in an independent cell or in the mucous or oxyntic cells. Careful studies in animals and man have not as yet disclosed any cells or group of granules, the special

function of which it is to secrete antianemic principle. I have made such studies under supervision and I have carefully reviewed (15, 32) the histological work of others as well as special staining methods without being able to shed any light on the exact locus of intrinsic factor formation. Surely the cells of the pyloric gland region have no distinguishing granular characteristics. On the other hand, there are many correlations between intrinsic factor and acid secretions to stimulate the imagination and to suggest investigations. These are the inactivating property of pepsin which is a secretion primarily of the fundus glands, the practically constant association of achylia gastrica and pernicious anemia, the report of a possible association between polycythemia and duodenal ulcer, the absence of ulcer in pernicious anemia and the demonstration that destruction of oxyntic cell tissue by pituitary extracts, as noted by Dodds and his group, with the production of achylia and a macrocytic blood picture in rabbits, at least suggest that the oxyntic cell reacts in direct proportion to the amount of antianemic factor secretion and it is not a far cry to suspect that this same cell may have 2 functions, one an external secretion of hydrochloric acid, the other secretion, primarily internal, of antianemic principle.

The unusual characteristics of the oxyntic cells have been observed by authoritative investigators of the histology of the cells of the gastric glands. For example, it is pointed out that each possesses a remarkable system of secretory canaliculi which discharges into the lumen of the gland. Might this possibly suggest internal secretion? Structural differences corresponding to physiological changes are not easily made out. The parietal cells seem not to undergo any morphological changes in connection with the various stages of functional activity.

Evidence suggestive of linking the manufacture of gastrin with the "mucoid" cells of the glands of Brunner, as well as with the pyloric glands of the stomach has been advanced by Murray (33). Murray found that when that part of the duodenum which contains Brunner's glands is used the secretion by the stomach is greater, more HCl and pepsin being produced. When parts that do not contain Brunner's glands are used the effect is insignificant in almost every case. Murray excluded the effect of histamine in these experiments for histamine given intravenously in cats causes practically no response. It must be recalled that Brunner's glands are exactly those to which antianemic potency has been attributed by Meulengracht. Therefore, since the stimulation of acid and pepsin secretions are brought about by a hormonal mechanism, it seems plausible to assume a similar mechanism for intrinsic factor or antianemic principle. Moreover, Aschner and Grossman (34) point out that extracts of the duodenal mucosa containing Brunner's glands injected intravenously cause secretion of pepsin and hydrochloric acid by the stomach, thus resembling antral glands in function. It becomes clear that functionally and histologically the pylorus and duodenum are related.

Furthermore, it is interesting in this connection to recall the studies of Downs and Eddy (35) on the influence of secretin on the number of erythrocytes in the circulating blood of rabbits. They were able to demonstrate a stimulating effect by secretin presumably upon bone marrow. They also observed that the subcutaneous administration of secretin to anemic

animals produced a much more rapid improvement than could be obtained by dietary adjustment alone. These experiments deserve further study.

In his original researches Castle pointed out that the intrinsic factor is not present in the duodenal contents from which gastric juice had been excluded. If duodenal substance has antianemic potency and if duodenal contents do not have such potency then either the antianemic substance is secreted internally or the duodenal cells secrete a secretin-like material which when absorbed stimulates secretion of antianemic principle in the gastric contents.

At this point it should be stressed that the absence of pernicious anemia after gastrectomy is due to the fact that all oxyntic tissue is not removed from the stomach (partial gastrectomy) or even when it is, which is rare, aberrant oxyntic tissue is still stimulated to secrete by the pyloroduodenal hormone. Moreover, complete removal of the pylorus still leaves the duodenum which apparently has similar properties so far as the secretions under discussion are concerned.

CONCLUSION

It becomes evident from the preceding material that the problem of "gastrin" remains a disputed one as we have already indicated. It cannot be denied, however, that the glands of Brunner and the pyloric glands have similar functions with respect to hematopoiesis. The cells of these regions have different functions from those of the fundus according to most authorities. If, therefore, antianemic potency is proved to be present in the fundus glands then it would seem likely that the pyloric gland region with its antianemic potency demands a different explanation of its mechanism of action than the replacement of actual antianemic material. That different mechanism suggests itself; namely, a gastric secretin analogous to pancreatic secretin.

It is for these reasons that we have had the courage to hypothesize the presence of a pyloroduodenal hormone which activates oxyntic cell secretion of intrinsic factor. A disturbance in this mechanism would result in a true macrocytic anemia, that is, one in which the antianemic principle is absent either as a result of loss of the activating pyloroduodenal hormone or as the result of non-functioning oxyntic cells (including aberrant tissues). However, there is another large group of conditions in which a macrocytic anemia may occur; these are dietary deficiencies; in other words, purely the result of an absence of extrinsic factor. The latter group are not true pernicious anemia since the intrinsic factor mechanism is still present but is interfered with by a debility due to dietary lack. Others concur in this explanation. Such macrocytic anemias, if not of too long standing, respond quickly to the administration of the substance responsible for the dietary lack; the true pernicious anemia may be an end-result of extrinsic factor deficiency only because the anti-anemic principle secretion is interfered with by general glandular asthenia.

PEPSIN HYPOTHESIS

Pepsin is secreted mainly if not entirely by the fundus of the stomach. Pepsin may antagonize intrinsic factor potency of the fundus.

PEPSIN. CLINICAL AND EXPERIMENTAL DATA

Histological studies of gastric and duodenal cells

lead to the conclusion that the fundus may possibly elaborate the intrinsic factor but that its impotency in clinical tests may be due entirely to its pepsin content. When physiological investigations are added to these it is interesting to note that the very cells to which are attributed those properties necessary to combat pernicious anemia are also attributed the possession of a hormone capable of stimulating hydrochloric acid and pepsin secretions. If acid and pepsin secretion are brought about, at least in part, by this humoral mechanism, it follows that the antianemic principle or intrinsic factor may also possibly result from a similar mechanism.

As a result of Meulengracht's work there is prepared in Denmark a commercial powder, known as Pylorin, which represents the pyloric-gland region. It has about the same activity as Ventriculin. However, whole stomach (Ventriculin) should be less potent than pyloric-gland stomach unless the fundus has anti-anemic potency; otherwise the lack of potency in the fundus would diminish the potency of the whole stomach preparation. Moreover, if Greenspon's conception of the importance of pepsin is confirmed then it is that substance which inactivates fundus anti-pernicious anemia potency inasmuch as pepsin is so predominant in fundus tissue. Both Ventriculin and Pylorin have proteinaceous muscularis to act as an adsorbent of pepsin according to Greenspon, or as a source of extrinsic factor according to Castle.

We have reported elsewhere (36) our studies on the rôle of pepsin in pernicious anemia. Our materials, consisting of cardiac, fundic, pyloric and whole stomach mucosae were depepsinized according to the method recommended. Interestingly enough, as far back as 1922, Lim (21) had observed that the activity of the extracts which he used in producing gastric secretion depended in a measure on their mode of preparation. The order of potency of extracts of the mucous membrane of the stomach and small intestine he found to be of the following descending order: pyloric, cardiac, duodenal, fundic, jejunal and ileal but he believed he could change the order of potency by adopting different methods of extraction. Perhaps this helps to account for the confusing reports of Henning and Brugsch (37) (1931), Gutzeit and Hermann (38) (1931), Henning and Stieger (39) (1930) and later in 1934, Henning (40), regarding the comparative potency of cardia, fundus, pylorus and duodenum. Finally, however, the impression is gained that the pylorus is more potent than the other portions as regards its effect in combatting pernicious anemia. Meulengracht (20) in 1935 reiterated this conclusion. Nevertheless, the mere fact that fundus mucosa was found to have some potency is important for it suggests that perhaps after all the presence of pepsin may interfere with the activity of fundus tissue. For example, Henning and Stieger (1930) reported that by administering the mucous membrane of the body of the stomach and that of the antrum pyloricum separately they found that both possessed the same blood regenerating power, and by proving that neither the one nor the other possessed a peptic ferment of any account *in vitro*, they believed they had confirmed the assumption that the effect of the powder was independent of peptic digestion of protein and was a primary and direct one on blood regeneration.

To test the hypothesis that pepsin is antagonistic to the antipernicious anemia factor in stomach we

treated 3 patients with pernicious anemia with depepsinized whole stomach mucosa and depepsinized fundus and pylorus mucosa, obtained from the hog's stomach under conditions considered proper for preserving anti-pernicious anemia potency. We were unable to establish any effectiveness in these preparations alone or with the addition of extrinsic factor. One exception was noted in the use of depepsinized pyloric mucosa which manifested a minimal, though definite, antipernicious anemia activity when the extrinsic factor was added. However, we have reason to doubt the possibility of completely depepsinizing fundus tissues by present methods and we suggest that the process of depepsinization may not always result in the same end-product. In one instance an active product may be obtained, in another an inactive one. Further studies support this belief. Consequently, unless disproved, Greenspon's demonstration of the antagonism of pepsin toward the antipernicious anemia factor (Castle's intrinsic factor) considered along with the known adsorptive capacity of protein and coupled with the histological knowledge of peptic cell predominance in the fundus of the stomach, all suggest a rôle for the fundus in pernicious anemia.

In view of the inactivity of our depepsinized products we questioned the status of intestinal permeability. However, the response to products of known potency, though submaximal, was enough to rule out the factor of intestinal impermeability. The possibility seemed apparent that the process of depepsinization could have inactivated the intrinsic factor. There was no doubt as to the adequacy of our sources of extrinsic factor. We proceeded to treat a patient (41) with typical pernicious anemia with simple desiccated stomach mucosa without any attempt being made to remove the pepsin or to go through the various extractions as described by Greenspon. This preparation proved to be completely satisfactory as a source of intrinsic factor and we, therefore, assumed that the process of depepsinization destroyed rather than enhanced the potency of these preparations. It is important to keep clearly in mind that even if the process of depepsinization inactivated the antipernicious anemia potency of these preparations that result does not necessarily mean that the absence of pepsin *per se* decreases the potency. In other words, a distinction must be made between the physico-chemical changes occurring during depepsinization and the theoretic removal of pepsin without subjecting the mucosa to any changes which might influence the antipernicious anemia potency.

We decided to repeat the administration of depepsinized preparations in increased dosage to two other patients in order to be sure that the maximum dosage of 40 grams each day, as already reported, was sufficient. Two patients were fed with 50 grams of depepsinized material each day. This would insure adequate dosage. Both patients were ideal for the experiment not only because their counts were low but also because they represented typical uncomplicated cases (no neurological signs or symptoms) of pernicious anemia. The first patient's blood did not respond to adequate dosage of depepsinized pylorus mucosa administered orally along with the extrinsic factor. On the other hand, oral and intramuscular therapy of known potency produced a characteristic response.

Curiously enough, the depepsinized fundus material

administered in the same manner was followed by a reticulocyte response of 7% on the 6th day after the onset of treatment. Whether this response, in the light of our previous data, was due to depepsinized fundus mucosa or to some extraneous factor or was spontaneous, it is difficult to determine with certainty. The expected maximum reticulocyte percentage, after desiccated stomach given orally, is about 40% for the level of this patient's blood. The response, therefore, is distinctly minimal. Nevertheless, is it not possible that depepsinized fundus material has antipernicious potency and that the reaction of this patient bears out our predictions that the process of depepsinization does not always result in the same end-product, that the overwhelming presence of pepsin in the fundus conceals its hematopoietic function and that the process of depepsinization rather than the absence of pepsin may account for the inactivation of intrinsic factor? This is further supported by the observation that one patient treated with depepsinized pylorus mucosa plus extrinsic factor led us to conclude that pylorus mucosa had hematopoietic potency whereas a second patient treated with the same material prepared at another time did not react. On the other hand, a patient treated with depepsinized fundus mucosa led us to conclude that it was completely inactive whereas another patient reacted to the same material prepared at another time. Further studies are needed to bring these rather confusing results to a definite and perhaps significant reconciliation. If fundus tissue has antipernicious anemia activity then this evidence supports our hypothesis concerning the action of a pyloroduodenal hormone. It is hardly possible that the increased dosage helps us explain our results since both pylorus and fundus were administered in equal doses in both studies.

Further studies of depepsinized stomach mucosa were made with pigeons but we have purposely excluded that data not only because it is controversial but because there is not sufficient time to present it adequately. I hope to do so on another occasion.

CONCLUSION

The influence of pepsin on antipernicious anemia activity of gastric tissue cannot be disregarded. An understanding of its exact rôle will require further study.

THE CONCEPTION SUMMARIZED

Neutral red may be very useful as a specific test of oxyntic cell function. At the same time it seems to detect a more minute degree of oxyntic cell viability than any other test at our disposal.

The study of neutral red excretion also suggests a pyloric control factor in oxyntic cell activity. Studies of pyloric extracts suggest the same conclusion. Since pylorus and duodenum are so intimately interrelated functionally and anatomically the hypothesis is offered that a pyloroduodenal hormone may regulate oxyntic cell activity. But pylorus and duodenum are also important in providing pernicious anemia-preventive factor. The likelihood that this activity of the pyloroduodenal region is entirely separate from the hormonal function appears to be remote. Therefore, the effort is made to demonstrate an interrelationship between all gastric secretions including the intrinsic factor.

Moreover, pepsin is antagonistic to anti-pernicious anemia activity. But pepsin is secreted by the fundus

of the stomach. If depepsinized fundus substance is potent in pernicious anemia then its mechanism of action must be different from depepsinized pylorus substance. Upon this demonstration the hypothesis of a pyloroduodenal hormone may also be substantiated.

DISCUSSION

DR. BORIS P. BABKIN (Montreal, Canada): I listened with great interest to your paper, Dr. Morrison. I don't think that I can discuss the anti-anemic factor because

the problems in which I am interested are rather far from this field. In some of your results, however, I am very interested. Thus, for instance, you have seen that the volume of the secretion depends greatly upon the activity of the parietal cells. We came to the same conclusion, which was based upon some different experiments. We believe that the whole fluid of the gastric juice is practically supplied by the parietal cells. The peptic, mucoid and mucous cells seem to secrete very little fluid. Again, in the case of a gastritis, you found in the gastric contents pepsin, but the amount of fluid was extremely small. In other words under these circumstances for some reason only the function of the parietal cells was paralyzed.

With regard to the pyloric hormone, I was glad to hear that although you couldn't purify it completely from histamine, it seems you are on the way to get something which is not histamine. As I have previously stated, I could never agree that the pyloric hormone is histamine. Histamine undoubtedly plays a certain part in the regulation of the gastric secretion, namely, in the nervous phase, but probably not in the chemical phase. There is something else which acts as a hormone during the chemical phase. Possibly it is the substance which Dr. Komarov extracted from the pyloric mucosa using trichloroacetic acid.

DR. SAMUEL MORRISON (Baltimore, Maryland., closing the discussion): I have no remarks to add except to thank Dr. Babkin for his discussion.

Editorials

A NEW METHOD FOR DETECTING ULCERATION OF THE DIGESTIVE TRACT

ONE of the most interesting suggestions recently made in the field of gastro-enterology is that of Dr. E. E. Woldman of Cleveland, who got the idea that when a patient has an ulcerated area in the bowel, the normal high degree of impermeability of the mucosa to many substances should be impaired. Reasoning along these lines I have long suspected that when a person who has always been able to eat some food, such as crab, with comfort, suddenly becomes highly allergic to it, it is because the formation of an ulcer has opened up a path through which much of the crab protein has gone unchanged through the liver into the blood. Somewhat against this theory, however, is the fact that during a study of the food-sensitiveness of 500 persons, I gained a strong impression that persons with ulcer and cancer of the stomach were particularly free from severe forms of food-sensitiveness.

At any rate, Woldman has devised a test in which a little phenolphthalein, dissolved first in alcohol and then in a little water, is drunk on an empty stomach. If the mucosa of the digestive tract is ulcerated, some of the phenolphthalein promptly goes through into the blood and then into the urine, where it can easily be detected. In many tests Woldman has found that the new procedure agrees well with roentgenologic reports indicating the presence of breaks in the gastro-intestinal lining, and in some cases the method proved to be very helpful. It may enable physicians to tell when a deformity in the duodenum means the presence of an open ulcer, and it may be useful in telling when an ulcer has healed and the patient can be freed from dietary restrictions.

If, as now appears, a negative test can rule out the presence of cancer in the digestive tract, we will have a most valuable tool added to our diagnostic kit.

Everyone will probably now start using the test, and within a few months we ought to know how useful and how trustworthy it is.

Walter C. Alvarez, Rochester.

SUGGESTIONS FOR A NEW SCIENCE

A NEW and promising field for research now awaits opening up and cultivation, and this is the art of so treating certain foods like beans and cabbage that they will lose much or all of their harmfulness to many sensitive men and women. That something can be done along this line is suggested by a number of facts:

As everyone knows, cooking greatly improves the digestibility of a number of foods, not only by breaking up cellulose partitions but also by altering irritant or somewhat poisonous substances. Thus apples, which when eaten raw cause discomfort in a large percentage of persons, when cooked appear usually to be harmless. During a study of food-sensitiveness made by Hinshaw and me, we met a number of intelligent persons who said that so far as they were concerned, the paring of certain foods, such as cucumbers, or the soaking of them in water or vinegar, or the cooking of them in a certain way, would render them harmless. Why shouldn't more research be done along this line, and might it not be possible to find some way of destroying or dissolving or altering chemically the substances in beans and other foods that cause them to be flatulent?

Curiously, cooking brings out the harmful properties

of cabbage, and many persons who can digest cole slaw cannot handle cooked cabbage with any comfort.

Search should be made for ways of "denaturing" the proteins or other substances in foods which injure so many allergic persons. It is known, for instance, that the evaporation or drying or fermenting or even the boiling of milk makes it less harmful to some persons who otherwise could not drink it with comfort. Some wheat sensitive persons are able to take bread which has been largely dextrinized in the oven. Recently the unpleasant taste has been removed from soy beans. In ages past primitive savages in Africa learned how to take the poison out of the cassava root. Cooking tends to destroy the Solanin which sometimes severely poisons persons who eat raw sweet potatoes. In recent years chemists have learned to take most of the caffeine out of coffee. In the manufacture of cocoa the fat is removed. Many other examples of such refining of foods might be mentioned. One of the commonest of these processes is the bolting of white flour with the mechanical removal of the husk and also of the germ which contains oils that interfere with the keeping qualities of the flour.

It would seem that after having made such good beginnings in the way of improving the digestibility of foods and in removing toxic substances, man ought to be able to go on to even greater accomplishments.

Walter C. Alvarez, Rochester.

NEW LIGHT ON THE NATURE OF THE GASTRO-INTESTINAL FERMENTS

OF great interest to the gastro-enterologist is the article on "The formation of enzymes" by Northrop in the January, 1937, number of "Physiological Reviews" (page 144). As will be remembered, Northrop was the first man to obtain crystalline pepsin, and, with Kunitz, to crystallize trypsin. These substances have now been shown to be proteins. Northrop has been much interested in studying those slight changes in an inactive protein which result in the formation of an active enzyme. Under certain conditions the reaction is autocatalytic; in other words, some enzymes possess the power to form themselves from inert proteins.

Already some insight has been gained into the chemistry of the activation of pepsin. Thus, it has been shown that acetylation of the primary amino groups of pepsin has no measurable effect on its activity, while acetylation of other groups, and probably particularly tyrosine, or iodination of the tyrosine results in loss of activity.

Long ago Heidenhain and Kühne showed that freshly secreted pancreatic juice is inactive, and it was assumed that the enzymes were secreted in an inactive form. The formation of the active enzymes from inactive pancreatic juice or from inactive extracts of pancreas has been studied extensively, but until recently the reports in the literature were confusing and contradictory. Northrop showed that this was due to the fact that the work had all been done with crude preparations containing mixtures of the proferments and inhibitors. Since small admixtures of these inhibitors markedly can influence the processes of activation, the experiments would never come out the same way until the proferment was isolated and crystallized several times in succession. When in this way the

chymotrypsinogen is freed from inhibitor and trypsinogen, its activation by trypsin becomes a clear-cut and reproducible reaction. The rate is proportional to the trypsin concentration and also to the chymotrypsinogen concentration.

The rate of activation by trypsin is affected by the acidity of the solution in the same way as is the rate of digestion of other proteins by trypsin, so that the reaction appears to be analogous to ordinary protein hydrolysis. There is one striking difference, however, in that, so far as Northrop and his coworkers have been able to determine, nothing is split from the chymotrypsinogen molecule although there is an increase of five amino groups per mol. The formation of the active from the inactive form of chymotrypsin, therefore, appears to be due to the opening of a peptide ring.

As in the case of chymotrypsinogen, the activation of trypsinogen changes markedly after the purification and crystallization of the substance. Amorphous preparations are stable in solution and can only be activated by the addition of kinase, large quantities of trypsin, or concentrated solutions of magnesium or ammonium sulfate. After crystallization, however, the inactive protein changes rapidly into the active enzyme as soon as it is dissolved in a neutral solution. The reason for the absence of such change in amorphous preparations of the proferment is that they contain traces of an inhibitor which prevents the autocatalytic reaction from taking place. As soon as this inhibitor is removed by crystallization the addition of a minute quantity of trypsin will start the activation reaction, which then proceeds autocatalytically.

Langley showed that pepsin existed in the gastric mucosa in a form which differed from that of the active enzyme in that it was much more resistant to alkali. Herriott has recently succeeded in isolating and crystallizing this substance. It has no proteolytic activity but in slightly acid solution it becomes converted into active pepsin. The reaction at pH 4.65 is autocatalytic and hence is caused by pepsin itself. So far as is known, pepsin attacks only peptide linkages so that there is reason to believe that the rupture of one or more peptide links in the protein proferment leads to the formation of the active enzyme.

While on the subject of the digestive ferments, the reader would do well to turn back to the eleventh volume of "Physiological Reviews" to a most interesting article by Waldschmidt-Leitz on "The mode of action and differentiation of proteolytic enzymes." He divides the proteolytic enzymes into proteinases and peptidases, and the proteinases into pepsinases, trypsinases, and papainases. According to Northrop (*Naturwissenschaften*, 11:713, 1923) the pepsinases react with protein cations, the trypsinases, with anions. The papainases appear to react with isoelectric protein. The peptide-splitting enzymes can be divided into carboxypolypeptidases and aminopolypeptidases, dipeptidases, and amino-peptidase or prolinase, according to the point of attack.

It is interesting to see how much exact information is now being obtained as to the chain-like way in which one ferment after another breaks down the protein molecule into simpler and simpler forms. Evidence accumulates to show that the action is a fairly simple chemical one and not a surface phenomenon as was once thought.

W. C. Alvarez, Rochester.

Abstracts

THE AMERICAN CONGRESS ON OBSTETRICS AND GYNECOLOGY

The first American Congress devoted to a consideration of medical, nursing and other problems associated with human reproduction will be held in Cleveland, Ohio, from September 11 to 15, 1939, inclusive. It will be designated as The American Congress on Obstetrics and Gynecology. The promotion and sponsorship of The Congress has been delegated to the American Committee on Maternal Welfare, Inc. The latter includes the following organizations in its membership:

American Association of Obstetricians, Gynecologists and Abdominal Surgeons

American College of Surgeons
American Gynecological Society
American Hospital Association
American Nurses Association
American Protestant Hospital Association

American Medical Association
Section on Obstetrics and Gynecology
American Public Health Association
Central Association of Obstetricians and Gynecologists

Chicago Maternity Center
Maternity Center Association of New York

National Medical Association
National League of Nursing
National Organization for Public Health Nursing

New England Obstetrical and Gynecological Society
Pacific Coast Society of Obstetrics and Gynecology

Southern Medical Association
U.S. Bureau of the Census
U.S. Children's Bureau
U.S. Public Health Service.

The purpose of this Congress is to afford opportunities for discussing and publicizing the problems associated with human reproduction and the health of women and new born babies. The value of more generally disseminated knowledge about the processes and problems of human reproduction and of the special diseases of the female generative organs and the new born is important in the maintenance of public health and therefore the interest of woman's welfare extends not only to the medical profession but to associated groups, including nurses, public health officials, hospital administrators, eugenists and many others.

Problems develop with the expansion of knowledge and these can be discussed most effectively at a meeting where many viewpoints can be intelligently discussed. Congresses,

international and national, afford the means of presenting and discussing the advances in various fields of science and bringing them to public attention. Obstetrics and gynecology in particular demand that wider association with allied groups, aside from the practitioners of medicine, which is so essential to the progress and welfare of the public. For these reasons the scope of the projected Congress has been extended beyond

that of similar assemblies held in the past and will devote much attention to the wider public welfare aspects of problems which have been considered frequently of purely medical interest.

The last International Congress of Obstetrics and Gynecology was held in Amsterdam, Holland, in May of the present year. Its success stimulated a desire to hold a subsequent one in five years in another European country. It is felt that the difficulties asso-

The most convenient and pleasant method of administering

Gastric Hydrochloric Acid

GLUTAN H-C-L

Indications. The literature shows GLUTAN H-C-L (Glutamic Acid Hydrochloride) to be a superior source of free hydrochloric acid in the treatment of gastric achlorhydria, hypochlorhydria, nervous anorexia, and in secondary anemias requiring a high protein diet, or whenever it is necessary to supplement or replace gastric hydrochloric acid.

Advantages. GLUTAN H-C-L is replacing the old methods of administering hydrochloric acid because—

No unpleasant taste.

No sipping through a glass tube.

No irritation of the esophagus or decalcification of the teeth.

Put up in capsules which may be carried in purse, handbag or pocket—patients appreciate this convenience factor.

Contains glutamic acid, a centuries old condiment—acting with hydrochloric acid the two produce a sense of well being after eating that is novel to patients who have long suffered from anorexia due to hypochlorhydria.

Supplied. GLUTAN H-C-L is put up in capsules, each of which is approximately equivalent to 10 minims of diluted hydrochloric acid U.S.P.

Bottles of 100, 500, and 1000 capsules.

Fill in and mail the attached coupon for a clinical sample and descriptive literature.

ciated with an international assembly, such as languages, expense, long distance travel, and limited participation, lack of common interest, call for a regional gathering in which opportunities for more general discussions would prevail. The proposed American Congress will therefore be modeled on different lines and include participation not only by medical groups but by those devoted, as already stated, to nursing, public health and institutional administration. The program will provide morning, after-

noon and evening sessions, the details of which will be announced subsequently.

National, sectional and local specialist societies have approved the Congress and have made contributions for its support. It is desired that a wider representation be secured through the medium of contributing memberships, the cost of which has been placed at five dollars. Application may be made at the office of the Congress, 650 Rush Street, Chicago, Illinois. Early application is desirable and will serve as

an indication of personal interest in the success of the undertaking.

In addition to the scientific sessions it is planned to provide for several evening meetings at which speakers of prominence will discuss the broader aspects of the subjects for the lay public. There will also be prepared a comprehensive exhibit — scientific, educational, technical and commercial, which should add greatly to the general interest of the Congress.

Cleveland is well adapted for a meeting of this kind. There are ample hotel facilities and the city is admirably located. The municipal auditorium, with suitable rooms for all types of meetings has been secured. Cleveland is a large railroad center and provides adequate transportation facilities, rendering access to the Congress easy from all parts of the United States and Canada.

The officers and committees thus far selected are as follows:

Executive Committee

Fred L. Adair, Chicago, Illinois, General Chairman.

Robert D. Mussey, Rochester, Minnesota, Vice-Chairman.

Sara B. Place, Chicago, Illinois, Secretary.

Rudolph W. Holmes, Chicago, Illinois, Treasurer.

Frederick H. Falls, Chicago, Illinois, Assistant Treasurer.

Program Committee

Frederick H. Falls, Chicago, Illinois, Chairman.

James R. McCord, Atlanta, Georgia, Secretary.

Medical Sub-committee — James R. McCord, Atlanta, Georgia, Chairman.

Nursing Sub-committee — Ruth Houlton, R.N., N.O.P.H.N., New York City.

Public Health Sub-committee — Howard D. Mettle, Indianapolis.

Hospital Administration Sub-committee —

Publicity and Advertising Committee
Paul Gebhard, Chicago, Illinois, Secretary.

Medical Publicity Sub-committee — George Kosmak, NYC, Chairman.

Promotion and Arrangements Committee

Joseph L. Baer, Chicago, Illinois, Chairman.

Educational and Scientific Exhibit Committee

Robert D. Mussey, Rochester, Minnesota, Chairman.

H. Close Hesseltine, Chicago, Illinois, Secretary.

Technical and Commercial Exhibit Committee

Bert W. Caldwell, Chicago, Illinois, Chairman.

Paul Gebhard, Chicago, Illinois, Secretary.

Budget and Finance Committee

Walter T. Dannreuther, New York City, Chairman.

Vomiting of pregnancy is a disturbance in carbohydrate metabolism. Hence the treatment by small carbohydrate meals at three-hour intervals. Karo added to foods and fluids prevents glycogen depletion and ketosis.

Enlarging of the uterus further produces reflex vomiting and unless carbohydrate is taken throughout the day to maintain the blood sugar at high levels, ketosis results. Karo helps provide the expectant mother with readily assimilated sugars preventive of ketosis.

Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

"Medical Aspects of Carcinoma of the Colon with Special Reference to the Early Diagnosis." *Southern Med. Jour.*, 31:1078-1087, Oct., 1938.

Carcinoma of the colon grows slowly, involves other structures relatively late, and offers a good prog-

nosis if radically removed early in its course. While some cases are silent in their symptomatology and others with symptoms are neglected by the patients themselves there are a number of cases which may be recognized earlier by the physician who will carefully consider apparently trivial complaints. While the greatest incidence of the disease is between the fiftieth and sixtieth years it may occur between the ages of ten and thirty and also in the very aged. Loss of weight when present is quite significant. Any unexplained progressive secondary anemia should always suggest the possibility of a colonic

malignancy. Dyspeptic symptoms usually vague and intermittent at first, evidence themselves in the form of anorexia, eructations, fullness, and flatulency, with nausea and vomiting in obstructive cases. Toxemia and cachexia usually occur late but in cases involving the cecum marked toxemia may be a relatively early symptom. Unexplained weakness and exhaustion are also often found.

Of especial significance is an alteration in the character of the stool. Constipation is the rule and a pre-existing constipation usually becomes more pronounced. Diarrhea may occur and should arouse particular suspicion if it alternates with constipation. The stool may contain mucus, blood, or pus and is often quite offensive. Unless there is obstruction the pain is usually mild and intermittent and often relieved by the expulsion of flatus. Obstruction is evidenced by increasing constipation and pain.

Profuse hemorrhage is rare but occult blood and bloody mucus are quite common. A palpable mass is a less frequent and rather late finding, usually difficult to demonstrate. It is very important to remember that no examination in case of suspected malignancy of the colon can be complete without a digital, sigmoidoscopic, and thorough X-ray study. The latter should include a barium enema, a barium meal. (In non-obstructed cases) and possibly air insufflation, and a single examination should not always be relied upon as final. (Rather detailed technique and interpretation are given).

In differential diagnosis regional ileitis, tuberculosis, ulcerative colitis, amebiasis, diverticulitis and benign strictures and growths must be considered.

Since surgery offers the only hope for a cure and since it must be done early to be successful a careful investigation for an evaluation of the symptoms presented is urged.

J. Duffy Hancock, Louisville.

READ, JOSEPH C.

"Review of One Hundred Cases of Acute Ruptured Peptic Ulcer." *Southern Surgeon*, 7:436-443, Oct., 1938.

This interesting series confirms most of the generally accepted views regarding ruptured ulcers. Ninety of the patients had sudden severe epigastric pain, sixty-three were nauseated and forty-five vomited. Although only twelve had previously consulted a physician for their symptoms ninety-two gave a history of some type of dyspepsia. Ninety-seven of the patients were males showing the usual preponderance of ninety per cent or more. Eighty-two of the cases occurred between the ages of twenty

LOSS of appetite without apparent cause is often due to vitamin-B₁ deficiency. Extra-dietary supplies of vitamin B₁ must be administered to break the vicious circle of relative increase in carbohydrate intake (because of distaste for other foods), increased vitamin-B₁ deficiency, increased anorexia. Berocca, crystalline vitamin B₁, 'Roche,' is speedily effective as a diagnostic and therapeutic measure. Dosage: for diagnosis (therapeutic test)—1 to 2 mg. Berocca, parenterally; for treatment—2 to 5 mg. Berocca a day, orally.

OTHER INDICATIONS FOR BEROCCA

Alcoholic Polyneuritis • Other Neuritis • Gastro-intestinal Hypomotility and Hypotonicity • Anemia • Certain Avitaminic Cardiac Malfunctions

PACKAGES. AMPLES, 1 cc — 1 mg. (at least 300 I. U.), boxes of 6 and 12; 1 cc — 10 mg. (at least 3000 I. U.), cartons of 6. ORAL TABLETS, 1 mg. (at least 300 I. U.), bottles of 25 and 100, 5 mg. (at least 1500 I. U.), bottles of 25. INJECTABLE SOLUTION, 1 cc — 10 mg. (at least 3000 I. U.), vials of 10 cc.

ACCURATE CONVENIENT ECONOMICAL B₁ THERAPY

RECENT ADVANCES IN THE SCIENCE OF NUTRITION

III. Some Attainments in the Fields of Vitamin A Research

● During the twenty-five years since its discovery, vitamin A has been the subject of much intensive research, first by the biochemist and physiologist, and later by the clinician and organic chemist. It may be of interest to describe briefly several of the achievements made in these various fields of research on vitamin A.

It has been found that vitamin A is unique among the vitamins thus far discovered. It is apparently the only vitamin produced solely by animal metabolism from precursors—certain carotenoid pigments—which are themselves solely the products of plant metabolism. The structure of the vitamin has been established and checked by syntheses of closely allied forms and probably of the pure vitamin itself (1).

Physiological and clinical researches have provided explanations of the mode of absorption of the vitamin and the mechanisms of transport and storage in the body (2). The specific pathological effects of varying degrees of vitamin A deficiency in humans have been extensively studied. Many of the older ideas concerning specific effects of vitamin A on man have been confirmed; some of the older beliefs have been dispelled (2).

Recent years have also brought improvements in assay methods for vitamin A (3). Common American foods have been sur-

veyed and their vitamin A values tabulated (4). Last but not least, authoritative estimates are at hand as to the quantitative requirements of children and adults for vitamin A (5). Such, in brief, are only a few of the important additions which have been made to our knowledge of this essential dietary factor. Today, students of nutrition favor the practice of "protective nutrition" in which the individual is maintained upon a diet calculated to supply all known dietary essentials—vitamin A included—in optimal amounts insofar as these amounts may be known. In specific instances, such dietaries must be supplemented by vitamin-rich materials. However, the prime consideration is to provide a properly formulated basic diet. In this connection, commercially canned foods are worthy of mention.

Modern canning procedures are practically without effect upon the vitamin A values of raw foods (3). The commercially canned varieties of foods prized for their vitamin A contents, therefore, lend themselves admirably to the formulation of protective diets. Not only because of their contributions of vitamin A, but also because of their ready availability, convenience and economy, these commercially canned foods provide one of the most valuable means whereby the American public may secure an optimal supply of the important dietary essential, vitamin A.

We want to make this series valuable to you, so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles. This is the forty-second in a series, which summarize, for your convenience, the conclusions about canned foods reached by authorities in nutritional research.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

and fifty, the youngest patient was eighteen and the oldest seventy-four, and four had had previous perforations. No seasonal influence was apparent and there was no history of trauma or straining in any instance. Gastric and duodenal ulcers were about equally divided.

All of the patients appeared acutely ill and eighty-one showed moderate or severe prostration. Everyone had some degree of upper abdominal rigidity and ninety-nine showed tenderness there. Rebound tenderness was usual and abdominal distention rare. Eighty-five per cent of the cases tested for obliteration of liver dullness gave positive evidence of this most impor-

tant sign. While there was considerable variation in the temperature, pulse, respiration, and white count the averages respectively were 98.4°, 92, 24, and 14,300 with 83% polys. X-ray examinations were not as conclusive as might be expected probably because of faulty technique.

The most common conditions to be considered in differential diagnosis are gall stone colic which is more localized in the right upper quadrant and accompanied by more restlessness, acute pancreatitis which presents profound shock and symptoms out of proportion to the physical findings, and acute appendicitis which usually does not have the extreme upper ab-

dominal rigidity but does show more frequent emesis.

All of the patients were subjected to surgery which was conservative (simple suture with or without excision of the ulcer) in ninety of the cases, and this plan is believed to give the lowest mortality in the hands of the average good surgeon. Post-operative measures included the use of the Levin tube, with or without suction, Fowler position, morphine, glucose and saline intravenously and subcutaneously, and warm drinks by mouth after several days.

By far the most frequent complication and cause of death was general peritonitis. Subphrenic abscess with or without peritonitis was the next most important factor in mortality. While others have reported better results with the use of spinal anesthesia the cases in this series showed no especial advantage over ether.

Thirty of the patients died, a mortality fairly in accord with other reports. The significant fact to be emphasized, however, is the direct relationship between mortality and time of operation the greatest increase becoming apparent after the perforation has been present more than nine hours. Early recognition of the disease by the family physician and prompt action by the surgeon are indispensable if an appreciable lowering of mortality is to be expected.

J. Duffy Hancock, Louisville.

COPELAND, SIDNEY MARVIN.

"The Clinical Aspects of Gastric Hemorrhage." *Southern Med. Jour.*, 31:1075-1078, Oct., 1938.

A bleeding ulcer is never to be lightly regarded. It carries a very definite mortality which is not always borne in mind. A good rule to remember is that the older the patient, the longer the history, and the more severe the symptoms, the more seriously is the hemorrhage to be considered. While the prognosis when hemorrhage is the first symptom of an acute ulceration is favorable, the ulceration may be quite chronic and symptomless until there is hemorrhage in which instance the outlook is not so promising. Mild cases where there are repeated small hemorrhages can usually be controlled without fatality whereas the massive ones, which may or may not be repeated, carry an inevitable mortality under the best plans of treatment.

Patients with bleeding ulcers should be hospitalized. Shock should be combated by morphine and glucose. The latter should be given intravenously preferably combined with a acacia rather than saline solution in order not to disturb the normal viscosity of the blood. Although there is some difference of opinion regarding the use of transfusions in massive hemor-

Strained Vegetables And Fruits Supply Infants With Significant Amounts of Minerals

Of the minerals which occur in the human body, those known to play physiological roles and to be indispensable for normal nutrition include sodium, potassium, calcium, magnesium, chlorine, iodine, phosphorus, sulphur, iron, manganese, copper and zinc, and apparently cobalt. It has been demonstrated that the total absence of any of these elements from an otherwise adequate diet will cause characteristic failure of nutrition in experimental animals.

Hanning reports that rapid curing of nutritional anemia in rats resulted from feeding adequate amounts of vegetables, or the equivalent quantities of iron and copper salts. (1)

Iron is not contained in either cow's milk or human milk in amounts adequate to meet the requirements of a normal infant. (2) Rapid growth and increased production of blood in the newborn infant depend upon a reserve of iron in the liver. A 2-ounce feeding of Gerber's Strained Prunes supplies 2.8 milligrams of iron. A 2-ounce feeding of Gerber's Strained Liver Soup supplies 1.6 milligrams of iron. (3)

In a study by Glazier in which 231 infants were observed he concludes, "A full diet which includes cod liver oil, orange juice, cereals, egg yolk, strained fruits and strained vegetables, given during the second and third months of infancy, produces a better state of nutrition and better food and bowel habits, because: it contains more nearly adequate amounts of vitamins A, B, C, and D; it provides bulk to the stool, eliminating an important cause for constipation in infants; and it accustoms the infant to solid food early in life, thus improving its food habits." (3)

Care is taken to conserve all minerals which are present in the raw products used in Gerber's Strained Foods. Their calcium, phosphorus and iron content are measured by analysis of samples selected from the entire season's pack, and averaged. These analyses are supplied on request.

Free on request: Analyses of mineral and vitamin content of Gerber Strained Foods. Also recent reprints. Gerber Products Co., Dept. 3311, Fremont, Michigan. (In Canada, Gerber's are grown and packed by Fine Foods of Canada, Ltd., Tecumseh, Ont.)

HEMATINIC PLASTULES

Thrifty and Effective

This effective iron medication is available, on your prescription, at a cost of only a few pennies per day!

More than two weeks' treatment with Fifty Hematinic Plastules Plain may be obtained at an average cost of less than one dollar.

Each Hematinic Plastule Plain provides five grains of ferrous iron and the vitamin B complex of concentrated yeast.

A marked improvement attends the use of Hematinic Plastules in cases of hypochromic anemia. They are well tolerated and easy to take.

TWO TYPES

Hematinic Plastules Plain

Hematinic Plastules with Liver Concentrate

THE BOVININE COMPANY • 8134 McCORMICK BOULEVARD • CHICAGO, ILLINOIS

rhage it seems more reasonable to use them. Nothing should be given by mouth the first twenty-four hours, only small amounts of ice water and perhaps non-residue fluids during the second twenty-four, afterwards a modified sippy diet if improvement continues. The use of coagulants such as snake venom, Vitamin C, and coagulin is harmless but of unproven value. Gastric lavage is indicated only for massive dilatation and the solution then used should be ice water.

Immediate surgery is indicated only for massive repeated hemorrhages. The indications for subsequent elective surgery are debatable. While it does not offer absolute protection against future hemorrhage it does

offer it to a high degree, and Eusterman and Balfour are quoted as saying that the possibility of serious consequences from subsequent bleeding in cases in which no operation is performed is greater than the risk of surgery plus its failure to protect against further hemorrhages.

J. Duffy Hancock, Louisville.

PORTIS, SIDNEY A.

Medical Treatment of Patients with Jaundice. Illinois Med. Jour., 74:249-253, Sept., 1938.

The type of jaundice most commonly seen is that which is associated with bile tract disease and gives a biphasic van den Bergh reaction with an icterus index above 20 as a rule.

Obstruction of the bile passages was previously thought to be the most common cause of jaundice, but increasing knowledge of liver disease has shown that toxic and infectious jaundice are the more common forms. By far the most common cause for the infectious and toxic type is cholecystitis with some corresponding degree of hepatitis.

The physiologic methods of evaluating liver function are for clinical purposes three in number: first, the amount of bilirubinemia; second the cholesterol ester fraction of total cholesterol; third, the total serum protein and albumin globulin ratio. The degree of bilirubinemia is expressed as the icterus index. Approximately 70% of the cholesterol in the blood is in the form of the ester, and when it goes below 50%, it is indicative of definite liver damage. The normal relation of albumin to globulin in the blood stream is four or three to one. In cases of liver damage this may be reduced to a one to one ratio or even to a one to two basis. It must be remembered that in protein loss, particularly with nephrosis, a similar albumin globulin ratio may exist.

Ten per cent glucose in saline or water intravenously is an ideal way to supply the liver with sufficient carbohydrate. There is no indication for the use of insulin in non-diabetics.

In the presence of jaundice one should withhold surgery until it subsides to a near normal level and other physiological methods indicate evidence of an increased liver reserve. All patients with gall stones, unless they are poor surgical risks, should be treated surgically. There is no urgency for surgery in a gradually increasing jaundice, especially if one is fairly certain it is not an obstructive or mechanical type of jaundice.

In treating patients with liver disease and associated jaundice, conservatism should be the better part of one's valor.

Hanes M. Fowler, Fort Wayne.

DANN, MARGARET AND COWGILL, GEORGE R.

Influence of Diarrhea on the Vitamin B₁ Requirement. Arch. Int. Med., v, 62, 136-150, July, 1938.

This continues the quantitative studies of B₁ requirement carried on by Dr. Cowgill and his coworkers. Anorexia has been chosen as an indicator of B₁ deficiency because it appears early before there have been grave changes in animal metabolism. Previous experiments demonstrated that the B₁ requirement of different species is a function of body weight and metabolic rate, that exercise, fever and diuresis increase B₁ need.

In this study young mongrel dogs were given an excess of B₁ to satur-

Where Salicylates are indicated

Provides you with an improved formula, a combined salicylate-iodide effect together with protective alkali buffers.

Provides your patient with an acceptable, effervescent form, easy to take, quickly effective, well tolerated.

THE FORMULA:

Each tablet contains

Sodium Salicylate	7½ grs.	Citric Acid	17 grs.
Sodium Iodide	1 gr.	Sodium Bicarbonate	.25 grs.

Note quick relief from pain and muscle spasm following the use of Salici-Vess. Tubes of 30.

Also available—Aspir-Vess (aspirin with alkali buffers); and Alka-Vess (for safe alkalization).

KNOX CLINICAL NOTES

ONE OF A SERIES OF CORRESPONDENCE EXCHANGES WITH PHYSICIANS ABOUT KNOX GELATINE.

QUERY about the Allergic Manifestation of KNOX GELATINE

A doctor writes, "Would you kindly tell me from what sources the materials used in making Knox Gelatine are obtained? I am especially interested in whether or not it is all beef, all pork, all sheep, or a mixture of proteins from different animals; also is the manufacture constant as to the ingredients used? This is very important to me as I want to use it for special diets in allergic cases, and for this purpose the exact sources of a food must be known and unvaried."

A good example of a CONCENTRATED Knox Gelatine Recipe:

Knox Gelatine Laboratory REPLY

Knox Gelatine is scientifically prepared from carefully selected long, hard, shank *beef bones only*. Twenty-one control and laboratory tests are made throughout the process of its manufacture. As far as we know, no case of allergy has ever been traced to the use of Knox Gelatine.

—THE KNOX MILK STIR—

Place the contents of 4 envelopes of Knox Gelatine in an ordinary drinking glass. Add 4 ounces of cold milk and allow to soak for five minutes. Add 2 more ounces of milk and stir until thoroughly soaked. Then place glass in small cooking kettle of hot water until gelatine milk mixture is thoroughly dissolved. Add 2 more ounces of cold milk, which will bring the temperature to a satisfactory warm drink of about body heat. A tablespoonful of prune juice or a few drops of any bland flavor like vanilla may be added.

Total: 8 oz. liquid—about 250 calories

Sample and useful Dietary Booklets on Request Write Dept. 475

Why you should insist on Knox Sparkling Gelatine

Because Knox Gelatine is 85% protein in an easily digestible form—because it contains absolutely no sugar or other substances to cause gas or fermentation, Knox Gelatine should not be confused with factory-flavored, sugar-laden dessert powders. Knox is 100% pure U.S.P. gelatine. Knox Gelatine has been successfully used in the dietary of convalescents, anorexic, tubercular, diabetic, colitic, and aged patients.

JOHNSTOWN, NEW YORK

Arousing the DORMANT Appetite

• There is a sound foundation for the use of vitamin B₁ in cases in which marked and obstinate anorexia and accompanying symptoms point to a dietary deficiency. Even when the symptoms are less definite and characteristic, the administration of vitamin B₁ serves a doubly useful purpose: If the results are favorable they indicate the probability of a previous shortage of vitamin B₁; if they are negative they help to clear up the diagnosis. Through the synthetic production of vitamin B₁—Betaxin—this essential food factor is obtainable in a pure, stable, crystalline form. Betaxin is available in different dosages for peroral use and intramuscular injection.

HOW SUPPLIED:

Tablets of 0.1 mg., 0.5 mg., and 1 mg., bottles of 50; tablets of 5 mg., bottles of 25.

Elixir containing 5 mg. in each fluidounce, alcohol 9%, benzoic acid 0.1%, bottles of 8 fluidounces and 1 gallon.

Ampules of 1 mg. (1 cc.), boxes of 10 and 100; ampules of 10 mg. (1 cc.), boxes of 5; vials of 100 mg. (10 cc.).

charts giving the incidence of intestinal parasites according to age, sex, and race groups, also a chart showing the incidence in food handlers in Dallas, Texas.

Endameba histolytica was found to be the most prevalent pathogenic organism, being found in 97 persons for an incidence of 3.46%.

Hanes M. Fowler, Fort, Wayne.

DUTTON, L. O.

The Relationship Between Allergy and Organic Pathology of the Appendix. Texas State Jour. Med., 34:363-366, Sept., 1938.

The author presents two case re-

ports which substantiate his conception that allergic reactions in the appendix are probably a common etiological factor in the development of both acute and chronic appendicitis.

Mild allergic reactions can explain some of the pathologic changes found in the chronic appendix, and also the clinical manifestations of the disease. This is particularly true of the profound systemic symptoms that cannot be explained on the basis of the histologic findings alone. The edema incident to the allergic reaction certainly could account for all of the stasis of the lumen contents that would lead to damage to the mucosa. The irreversible necrosis of the allergic reaction

certainly would offer ample opportunity for bacterial invasion to occur. In other words, an easily understood initiating lesion is certainly an integral part of the allergic reaction. The author believes that by the combination of the allergic and the ineffective in the consideration of appendicitis, many of the unanswered questions concerning the disease may be answered.

Hanes M. Fowler, Fort Wayne.

HENCH, PHILIP S.

Effect of Spontaneous Jaundice on Rheumatoid Arthritis. British Med. Jour., pp. 394-398, Aug. 20, 1938.

Jaundice involves a physiological reaction which is antagonistic to the continuation of active symptoms of rheumatoid arthritis and primary fibrositis. With the onset of any one of several types, rather dramatic remissions in rheumatic symptoms, lasting from three to 104 weeks, occurred in nineteen cases of rheumatoid arthritis, in nine of primary intra-muscular or peri-articular fibrositis, in two of lumbo-sacral and sciatic pain, and in one of secondary hypertrophic arthritis of the hips. Remissions averaged (roughly) from two to three times the average duration of the jaundice and affected symptoms of active disease; residual articular thickening and disability from deformity were unaffected.

The phenomenon depends more on the quantity than on the quality (or type) of jaundice, a certain intensity of jaundice being required. Several methods involving the administration of various components of bile and the production of artificial jaundice and induced hyperbilirubinemia are being used in an attempt to reproduce the phenomenon.

CONWAY, F. M.

Impalement of the Rectum. S. G. O., Vol. 66, No. 2, pp. 222-226, Feb. 1, 1938

Impalement of the rectum is an unusual type of injury requiring immediate surgical treatment. Most of the reported cases have occurred following a fall from a hay loft, striking the handle of a pitch fork. Impalement may be the "pure type" in which the impaling object passes through the rectal wall from within outward, or the "atypical type" in which the wall of the bowel is perforated after the impaling object passes through the soft tissues of the perineum. In either type other injuries to such organs as the bladder, small intestine, or kidney may be found. Fistulae and abscesses may develop along the course of an atypical impalement.

The symptoms may not be marked

Choosing a Happy Medium . . .

EXICOL

(Oleic Acid and Bile Salts)

The most recent researches* again emphasize the marked fat-intolerance displayed by patients suffering from gall bladder disease, and the satisfactory therapeutic results on a low fat diet and bile salts. Contrary to recent advocates of high fat therapy, it is pointed out that overstimulation of the gall bladder, produced by such high fat diets is undesirable.

Exicol, containing a small quantity of fatty acid and bile salts, offers a solution to the controversial problem of biliary tract therapy. It is the most rational therapeutic agent in biliary disorders because—

1. It stimulates mild gall bladder contractions due to the fatty acid.
2. Increases bile secretion from 100 to 200% ** due to synergistic action of oleic acid and bile salts.
3. Makes high fat diets unnecessary.
4. Exicol is most effective as an aid in the treatment of chronic cholecystitis, biliary insufficiency and other non-surgical as well as post-surgical biliary tract disorders.

For the Aristocracy of Thought*

Your highly valued Journal is made to order for the aristocracy of thought of the Medical Profession of America . . . it has become a habit with me, and I would not care to miss a single issue.

The AMERICAN JOURNAL OF DIGESTIVE DISEASES

Was NOT established as a *vade mecum*, a news magazine, a humorous monthly nor a fictional alleviation for the jaded nerves of busy doctors . . . Most readers by this time have divined this point of policy, and have come to know that, month by month, this periodical gives a cross section of current and modern gastro-

enterological thought. It sees most of the manuscripts in this specialty: it prints all of them that are suitable . . . BETTER articles will be printed only when BETTER articles are written. The reader may confidently believe that at present the best work in gastro-enterology finds its way into these pages . . . Another way of saying that the management of this JOURNAL is seeking to perfect a really worth-while Archive in a most important field.

It is the firm intention of the Editorial Council that the pages of this Journal shall be kept FULL of important matter, and entirely EMPTY of all matter that is irrelevant . . .

Readers feel today that an important contribution to American Medicine is being, and will be, made through the agency of the American Journal of Digestive Diseases . . .

I am an admirer and reader of your excellent magazine.

You cannot improve on the editorial content—it is and should be, an outlet for scientific thought.

Material and format are excellent. I enjoy it very much because the articles are scientific.

It is certainly a well edited Journal and anyone who subscribes to it certainly gets his money's worth.

Quality brevity, educational value, scientific dignity, good typography and singleness of purpose are making friends in increasingly large numbers.

No Other Special Medical Journal Ever Made the Subscription Showing in 4 Years That Has Been Accorded to the American Journal of Digestive Diseases

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY?

The reasons are obvious—

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.

• This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases.

Spend \$6.00 per year or \$10.000 for two years NOW.

Constipation from Restricted Dietaries

When dietary restrictions reduce normal fecal bulk, constipation often follows. As a supplement to dietary limitation, Mucilose supplies bland, non digestible bulk which aids in maintaining normal peristalsis without interfering with the regulation of food intake.

MUCILOSE

is a hemicellulose (vegetable gum) derived from *Plantago loeflingii*, and subjected to intensive refining processes which remove intestinal irritants. It is hygroscopic, and by holding ingested water in the stool maintains proper fecal consistency, without possibility of anal leakage.

Mucilose is available in two forms, **Flakes** and **Granules**, and is as easy to take as a breakfast food. It should always be taken with enough water to maintain the essential optimum water balance in the bowel.

and proctoscopic examination may not reveal any abnormality.

Treatment is surgical. In some instances colostomy may be deemed advisable to hasten healing of extensive perineal lacerations.

The mortality is usually quite high; in some series more than a 71 per cent mortality has occurred.

Four figures, a detailed report of a case successfully treated, and a bibliography accompany the article.

Nelson M. Percy, Chicago.

HINES, LAURENCE E. AND FITZGERALD, BERTRAM.

Splenomegaly of the Banti Type. Report of a case with postmortem observations four years after splenectomy. Arch. Path., 26-1, 155, July, 1938.

The authors report the case of a man who presented the Banti syndrome whose spleen was removed in 1932, at the age of 45, and who died four years later from hemorrhage

from the rupture of an esophageal varix. No obstructive lesion of the portal circulation was found at operation, and the liver showed no evidence of cirrhosis. The health of the patient during the subsequent four years was not improved. The anemia continued from repeated hemorrhages. He died, as stated above, from a severe hemorrhage. At autopsy but little more could be found to explain the evident continued hypertension of the portal vein. The liver showed but a mild degree of intrahepatic peri-portal fibrosis, but it was associated with narrowing of the portal channels, which the author believed had to be regarded as the obstructive mechanism in this case.

FARRELL, J. I. AND LYMAN, Y.

Aseptic Uretero — Intestinal Anastomosis. S. G. O., Vol. 66, No. 3, pp. 657-662, March, 1938.

The author describes an aseptic method of uretero intestinal anastomosis in which a side to side suture is placed between the ureter and the submucosa of the bowel; the muscular layers having been pushed back. A loop of silk thread is then passed through the ureteral wall and the mucosa of the bowel at the points opposite those in the ureter. After the anastomosis is completed, using 00 chronic catgut sutures, the opening between the ureter and bowel is established by sawing through with the silk suture. The ureter is then clamped beyond the anastomosis and any leakage of the anastomosis is sutured over. The entire anastomosis is covered with the longitudinal muscle layer and peritoneum of the bowel.

The author points out several advantages of this method. They are: (1) no catheters, cautery or bowel preparation are necessary, (2) the two structures are firmly united before the opening is made, (3) a longitudinal opening larger than can be made by most methods may be made, (4) the bowel musculature is not cut and the circular layer acts as a sphincter for the ureter.

Four figures and a bibliography accompany the article.

WHAT IS CURD TENSION?

Curd knife used in measuring curd tension

The patient with gastric ulcers for whom you prescribe Pet Milk might be more appreciative of your choice of milk if he understood that a milk of low curd tension is very easily digested, having little or no irritative effect—and that the curd tension of Pet Milk is 90% less than that of ordinary milk.

There is interesting information on this subject in a special booklet which you might like to have, and which we should be glad to send you. It contains data on the curd tension of ordinary milk and Pet Milk, and a description of the method of determining the tension of each.

A detailed explanation is given of the manufacturing process which, in addition to reducing the curd tension of Pet Milk, makes it a uniformly rich and sterile milk, highly suitable for the dietary employed in the treatment of gastro-intestinal disorders.

To obtain booklets and samples of Pet Milk, use the coupon below.

structing the common duct, causing concentration of the bile and bile pigments with calcium deposit to make it opaque to X-rays. Injections of pitressin caused the stone in the ampulla to be dislodged and forced into the intestinal tract. Further injections of pitressin apparently caused more complete evacuation of the gall bladder by stimulating its contractions. These events were demonstrated by X-rays.

While admitting that no conclusions should be drawn from one case, the author suggests that the use of pitressin might well be considered in

the treatment of common duct obstruction by small biliary calculi.

HOFRICHTER, C. H.

Experiences with Protamine Zinc Insulin. Northwest Medicine, 37:218-223, July, 1938.

Protamine zinc insulin is as effectual as standard insulin in the metabolism of carbohydrate, but much slower in exerting its influence substitution of protamine insulin for standard insulin is best done gradually. Mild cases of diabetes do well on protamine zinc insulin. Severe cases do well if one remembers not to rely

upon it for quick action when this is necessary. The slowness with which protamine zinc insulin becomes available makes it undesirable as the chief therapeutic aid in severe acidosis with coma or in cases of progressing infections. Reactions when occurring with protamine insulin tend to be more severe and more prolonged. There is a tendency to irritate tissues at the site of injection in some cases. There is also a tendency to pocketing in the tissues with release under exercise in some cases. Six-hour fractionated urine specimens are a sensitive guide to case progress. In the face of infection the unit dosage of insulin may be much larger than when the individual is infection free.

Hanes M. Fowler, Fort Wayne.

THE THREE-FOLD ACTION OF *Creamalin* IN PEPTIC ULCER

Creamalin exerts its dependable healing influence on peptic ulcer in three phases of action which attest its rationale.

1. Its astringent action encourages the formation of fibrinous deposits over the lesion, thus intensifying clot formation.
2. By neutralizing 12 times its volume of N/10 HCl in less than 30 minutes, Creamalin depresses gastric acidity to the point where the activity of pepsin is inhibited, thus guarding the protective clot from proteolytic digestion.
3. Through its sustained acid-neutralizing influence, and because it does not lead to a secondary acid rise, Creamalin under sufficiently frequent oral administration maintains gastric acidity at a pH level of 4.5 to 5, at which healing of the ulcerous lesion progresses rapidly.

GHOSH, JAHARLAL.

The Value of Gastric Analysis in Clinical Diagnosis. Jour. Indian Med. Assoc., 7:509-514, June, 1938.

Analysis of gastric contents is undoubtedly a valuable method of investigation of the dyspepsias but possibly its value is usually over-estimated. Achlorhydria with presence of definite amount of lactic acid in the fasting contents is highly of cancer of the stomach. Hyperchlorhydria in a suspected case of ulcer is merely an additional point in favor of the probability but not at all pathognomonic of the condition. The typical climbing curve when obtained in such a case is suggestive of duodenal ulcer. Analysis of gastric contents materially helps in the diagnosis of anemias and subacute combined degeneration of the cord. The results of gastric analysis should always be interpreted with due regard for the history, physical findings and results of other special methods of investigation.

MARSHALL, GEO. R. AND WOOD, O. L.

Ischio-Anal Abscess Caused by Oxyuris Vermicularis. Northwest Med., 37:180-182, June, 1938.

The anatomic importance of the crypts of Morgagni as a harboring recess for oxyuris vermicularis and ova is brought out, especially those crypts elongated by infection and trauma. Intractability to treatment has been associated previously with the possibility of an appendiceal involvement but the importance of the anal crypts in this condition has not been mentioned or stressed. Therefore, the importance of anoscopic examination in these cases and inspection particularly of the anal crypts, is emphasized.

A case of ischio-anal abscess containing oxyuris vermicularis is reported.

Hanes M. Fowler, Fort Wayne.

PERSUASION WITHOUT URGING

There are occasions when the colon needs "persuasion" without "urging" to evacuate its contents, especially in children. This gentle prodding can be well accomplished with LORAGA, the plain mineral oil emulsion with agar-agar, noted for its exceptional palatability. The fine ingredients of Loraga are so thoroughly emulsified that freedom from oily after-taste is achieved without artificial flavoring and disguise. Loraga may be taken undiluted or diluted, it may be added to milk or to any other liquid or semi-solid food. It contains no sugar, alcohol or alkali. A good intestinal softener and lubricant, that unlike plain mineral oil, mixes thoroughly with the intestinal contents and stays mixed. It forms no pools, it causes no leakage.

Loraga is available in 16-ounce bottles.

LORAGA

Please write on your letterhead for a trial supply.

"BULK"
supplied by
Kellogg's
ALL-BRAN
stimulates
and facilitates
ELIMINATION

• Sufficient "bulk," supplied by food residues, has a double function in aiding elimination. It provides a mass that not only promotes a movement, but can be easily evacuated.

Kellogg's All-Bran also contains an appreciable quantity of vitamin B₁. According to medical authority, this vitamin exerts a beneficial effect on intestinal tonus.

For these reasons, Kellogg's All-Bran may be confidently recommended as an excellent laxative cereal in cases of constipation resulting from lack of "bulk." Made by Kellogg's in Battle Creek.

A NATURAL LAXATIVE CEREAL

PHILLIPS, JOHN ROBERTS.

Severe Hemorrhage of Peptic Ulcer Origin." Southern Surgeon, 7:407-411, Oct., 1938.

The generally accepted view that severe hemorrhage of peptic ulcer origin rarely is fatal is probably incorrect. Statistics quoted showed a mortality of five to fifteen per cent of ulcer patients who bled while under hospital care. It is important to realize that hemorrhage in patients over forty years of age is much more likely to be fatal than in younger ones because increasing sclerosis of the blood vessels tends to hold open the vessels once erosion has occurred. Medical and surgical management are not competitive and the former should always be used first. If, however, the bleeding persists or recurs in massive quantities within a few days, and especially if the patient is past forty, immediate operation is imperative. As anything less than a direct attack upon the bleeding vessels is usually inadequate rather extensive and hazardous procedures, such as partial gastrectomy or duodenectomy, will be indicated since the vessel will often be on the posterior wall perforating onto the pancreas with much scarring present. Transfusions are of course most useful during such treatment and may be given by multiple portals. Six interesting case reports are included.

J. Duffy Hancock, Louisville.

SMITH, RICHARD M.

Chronic Idiopathic Ulcerative Colitis in Children. New England Jour. of Med., 217, No. 14, 541-546, Sept., 1937.

A brief differential diagnosis of melena is given. The clinical course of chronic ulcerative colitis is described, progression of the disease with remissions occurring, associated with marked weight loss and anemia. He recognizes an insidious and an acute onset and reports an illustrative case of each.

An infectious origin is considered more likely though the diplostreptococcus described by Bargen is considered unproved.

Medical treatment may be classified under four headings:

1. Directed at the colon, sedatives as opium and bismuth, low residue diet, serum and vaccine.
2. Maintenance of adequate nutrition, high caloric diet with abundant vitamins, replacement of lost minerals.
3. Combatting anemia, transfusions, iron if borne.
4. Symptomatic, sedatives for pain.

Surgery is indicated because of the danger of perforation or of polyposis followed by malignancy. The time for surgery is when fibrosis begins as shown by the loss of haustrations, narrowing of the lumen. Ileostomies are considered permanent in adults, in children it may be possible to restore normal continuity in two or three years.

The end results in twenty-seven cases are tabulated.

Medical treatment, nine cases. Five well, two still acute. Two deaths, one of perforation, one of carcinoma.

Surgical treatment, eighteen cases. Nine alive, five closed. Nine deaths, two of perforation after ileostomy, one of perforation after colectomy, two of volvulus after ileostomy, one operative death with ileostomy, one acute ileitis after ileostomy, one peritonitis after closure, one tracheobronchitis two months after surgery.

The cases receiving medical treatment were generally milder. It is concluded that surgery, meaning ileostomy, offers the most in these cases and that it should not be delayed too long.

COMMENT

This paper does not emphasize the surgical risk that the figures given show. Too many of the deaths are the result of surgery, experience which has been duplicated elsewhere in this disease. Surgery did not prevent perforation in two cases, and the mortality of 50 per cent in the surgical group is not encouraging.

K. W. Benson.

Put the Patient's System to Work for Him!

The original scientific formula of Vi-Syneral, pictured above in symbolic form, was developed after 26 years of vitamin-mineral research by Dr. Casimir Funk and Dr. H. E. Dubin.

Prescribe

VI-SYNERAL

Insufficient vitamin-mineral intake—that's what may be slowing up the patient's recovery! Clinical experience now shows that a great number of ailments are entirely or partially due to vitamin-mineral short rations. Without adequate amounts of these important elements, vital to the health of every cell in the body, your patient cannot make the most of your therapy. Certainly, if the average diet lacks sufficient vitamins and minerals in "good health," how much greater the risk of protective food inadequacy during illness.

Put your patient's system to work for him by prescribing daily doses of Vi-Syneral*, the original multiple vitamin-mineral concentrate. Greater systemic vitality and resistance must assist recuperative power. Your specific medication acts under conditions most favorable for maximum results.

MINERALS WITH VITAMINS GIVE OPTIMAL RESULTS^{2,3}

VI-SYNERAL* contains all the definitely recognized vitamins, fortified with eight essential minerals because

...VITAMINS NEED ONE ANOTHER FOR BEST RESULTS

...MINERALS ARE ESSENTIAL TO OPTIMAL VITAMIN EFFECTIVENESS

...VITAMIN AND MINERAL DEFICIENCIES ARE MULTIPLE.

There is a standardized Vi-Syneral potency for every age group. Each box of 50 capsules equals the vitamin and mineral value of hundreds of pounds of fresh vegetables, fruit, milk and other foods.

For bland diet therapy, especially ULCER cases

... PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastrointestinal disorders is a deficient diet. Pablum is rich in a wide variety of the accessory food factors and can be fed over long periods of time without danger of gastrointestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than does farina and is an excellent source of vitamins B₁ and G. Also rich in calcium and phosphorus.

Requires no cooking. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Can also be used in a variety of appetizing dishes to enhance their vitamin and mineral values. Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal (farina), oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, reduced iron and sodium chloride.

Samples and literature sent on request of physicians.

KONSYL NON-HABIT FORMING

While KONSYL, the original concentrated vegetable mucilloid made from Plantago Ovata, is indicated in chronic constipation it is also of value in the treatment of the following conditions:

1. *In catarrhal colitis* caused by purgatives, nervous spasm of the bowel and in chronic irritation caused by coarse indigestible foods, Konyl by forming a soft bland non-irritating bulk will usually have a beneficial effect.
2. *Headaches.* There are many cases of headache, lethargy and dizziness that are due to colonic stasis, or clogging of the large bowel with fecal material. Konyl, by establishing regular climination, is usually of great benefit in these cases.
3. *Looseness of the bowels.* There are many cases of looseness of the bowel, especially of nervous origin, where Konyl by supplying a soft bulk absorbs excessive intestinal fluids and changes loose movements into soft or even formed stools.

Write for clinical test sample and literature.

Also manufacturers of L. A. FORMULA containing Lactose, Dextrin and Plantago Ovata Concentrate.

PROUTY, JAMES V.

Regional Enteritis. Jour. Iowa State Med. Soc., 27:379-382, Aug., 1938.

Regional enteritis may be encountered in an acute or chronic form. It may involve one or more areas in the jejunum, ileum, or colon. The etiology is unknown. The pathology consists of an acute or chronic nonspecific inflammatory process. The symptoms depend upon the severity, duration, extent and location of the lesions. They may simulate appendicitis, ulcerative colitis, obstruction, or malignancy. The preoperative diagnosis depends largely upon proper roentgen examination. The treatment is essentially surgical.

Hanes M. Fowler, Fort Wayne.

RAO, M. NARASIMHA.

Histidine and Peptic Ulcer. Jour. Indian Med. Assoc., 7:518, June, 1938.

In a series of sixteen cases of peptic ulcer treated with histidine 3 cases were classified as cured. In one case there was only symptomatic relief. Ten of the cases showed no improvement or otherwise. Two of the cases got definitely worse. Estimations of progress were based upon symptomatic, radiological and biochemical evidences, and the cases were "followed up" for one year after the treatment which consisted of an average of 21 to 25 daily intramuscular injections of 5 cc. of 4% histidine monohydrochloride.

Hanes M. Fowler, Fort Wayne.

VOEGLIN, WALTER L.

Some Novel Manifestations of Ascariasis. Northwest Med., 37:182-183, June, 1938.

This is a report of an unusual case of ascariasis in which the parasites migrated into the common bile duct, and up through the stomach into the esophagus and pharynx at times. The symptoms produced were upper right quadrant pain, polyphagia, pain in the chest, and foreign body sensation in the esophagus. The patient extracted one worm from her pharynx with her fingers. Caprakol and hexylresorcinol caused the evacuation of seven worms and disappearance of all symptoms.

Hanes M. Fowler, Fort Wayne.

At the meeting of the Central Society for Clinical Research (reported in the J. A. M. A., 110:687, 1938) Rynearson reported having been able to get rid of individual hypersensitivity to protamine zinc insulin either by giving histaminase by mouth or histamine injections.

W. C. Alvarez, Rochester.

AS ONE PHYSICIAN TO ANOTHER—

IN TREATING CONSTIPATION, THIS IS WHAT 9 PHYSICIANS OUT OF 10 WOULD SAY...

New habits of elimination, new dietary habits are the basis of most successful treatment. However, in aiding in the re-establishment of such habits, a bland pure mineral oil may often be most helpful. And now, in light of

recent studies upon the effects of Vitamin B-1 in the gastro-intestinal tract, this important food factor may be an essential in restoring normal tonus to the neuro-muscular mechanism of the intestines.

BOTH OF THESE IMPORTANT AIDS ARE PRESENT IN VITA NUJOL!

VITA NUJOL is a pleasant tasting mineral oil emulsion with pure crystalline Vitamin B-1 added. The concentration of the vitamin is such that the recommended average dose of Vita Nujol contains the average maintenance requirements for an adult (200 units).

VITA NUJOL will be found to be helpful not only in the treatment of constipation, but wherever Vitamin B-1 deficiency may be

a factor. This includes such conditions as loss of appetite, the toxemias of pregnancy and chronic alcoholism, gastric and duodenal ulcers, and many other common syndromes.

A postal card brings you free samples and descriptive literature. Stanco Incorporated, 2 Park Ave., New York, N. Y.

MCCULLOUGH, NORMAN B.

Vitamin C and Resistance of the Guinea Pig to Infection with Bacterium Necrophorum. Jour. of Infectious Diseases, 91, 34-53, July-Aug., 1938.

There is much contradiction in previous work relating Vitamin C to infection. Diets may have been deficient in other essentials. Crude sources of Vitamin C have been used. Virulent organisms have been used making survival period the only criterion.

It has been demonstrated that chronic C deficiency shortens the survival of the guinea pig with tuberculosis. Excess of the vitamin doesn't alter the course of the disease. Injections of streptococcus toxin will produce rheumatic fever like lesions in the scorbutic guinea pig. C reserves are lowered in febrile disease as might be expected from the increased metabolism. Vitamin C has antitoxic effect in diphtheria, and some protective action against anaphylactic shock.

Several strains of bacterium necrophorum (bacterium funduliforme) were isolated from cases of chronic ulcerative colitis. It is not assumed that these are the causative organisms. Fifty guinea pigs that had been kept seven days on a C deficient diet were inoculated in the abdominal wall, thirty-one developed low grade local infections not affecting body weight. Fifty controls on an adequate diet were unaffected by the inoculations.

Forty-five guinea pigs were just kept from having acute scurvy by minimal doses of Vitamin C. None developed infection following inoculation with bacterium necrophorum.

Bovine strains of bacterium necrophorum, slightly more pathogenic to the guinea pigs, were injected into normal and deficient guinea pigs. In the deficient animals the lesions were more severe and did now show a tendency to heal spontaneously. After seven days the deficient animals were given crystalline Vitamin C, those that were not moribund recovered rapidly from the scurvy and the infection.

It is concluded that a very severe grade of scurvy is necessary to reduce the resistance of the guinea pig to these organisms. In clinical practice Vitamin C deficiency must be marked to account for a low resistance to infection.

BROOKS, CLARK D., CLINTON, WM. R. AND ASHLEY, L. BYRON.

Primary Carcinoma of the Jejunum. Jour. Mich. State Med. Soc., 37:795-797, Sept., 1938.

Primary carcinoma of the jejunum is not only an infrequent lesion, but an interesting one as well, because of the difficulty in making an early diagnosis, the irregularity of the symptoms, and the unusual response to surgical treatment. The incidence is only 0.15 per cent of all gastrointestinal carcinomas, according to the most recent survey by Mayo and Nettrour.

Two cases are reported with descriptions of the symptoms, operation, and post-operative progress. Both cases made uneventful recoveries after operation, and are in good health twenty-eight and eighteen months, respectively, after operation.

colored and greasy and loss of weight is quite common. A preparation of dried bile is described which was found to be effective in relieving the symptoms commonly associated with lack of bile in the intestine, particularly anorexia. The dried bile also had a slightly laxative effect. It also forms a simple means of supplying additional bile so necessary for the absorption of Vitamin K in jaundiced patients.

Hanes M. Fowler, Fort Wayne.

BARNES, J. PEYTON.

Appendectomy Mortality.. Texas State Jour. Med., 34:360-363, Sept., 1938.

Every year 17,000 persons die from appendicitis peritonitis. Records of 228,598 appendectomies have been collected with a mortality rate of 1.09 per cent. Operation for non-ruptured appendix has a mortality of 0.8 per cent, practically the same as that for simple hernia repair. Operation for ruptured appendix has a mortality rate of 18.3 per cent, based on 13,965 cases.

The author feels that a prophylactic appendectomy is indicated if an individual has ever had a distinct attack of appendicitis, or if he presents symptoms which create a doubt as to the innocence of the appendix. The above figures, gathered from many hospitals and made by thousands of different doctors, prove definitely that the disease is more dangerous than the operation, even in the hands of the average operator.

Royal Metal Mfg. Co.

1131 S. Michigan Ave.,
CHICAGO
New York — Los Angeles — Toronto

Ulcerative Colitis with Some Suggestions for Treatment. Annals of Internal Med., 12:339-352, Sept., 1938.

A chiefly statistical study was made of the records of 871 patients who had thrombo-ulcerative colitis and who have been followed from 7 to 14 years after the first observation.

Predisposing factors and factors affecting relapses of the disease are chiefly the following: Upper respiratory infection, disease of childhood, dietary indiscretion, physical and mental fatigue, rectal or abdominal surgery, trauma, drastic catharsis, foci of infection with sepsis, exposure, dysentery epidemics, and pregnancy.

This disease may begin in an insidious manner. Again, it may come on suddenly, as a violent diarrhea without toxic symptoms, or it may start in a fulminating fashion, associated with marked toxemia, fever and all the concomitants of a severe septic process.

On the basis of its course, the disease can be readily divided into the following types: (1) mild throughout, (2) intermittent with declining severity, (3) septic with complete recovery, (4) constant without remission, (5) slowly progressive without remission, (6) intermittent with progressive severity, (7) insidious onset with slow progression, changing to a fulminating condition and ending fatally, and (8) fulminating throughout, ending fatally.

The major complications and sequelae of thrombo-ulcerative colitis include polyposis, stricture, perianal abscess—fistula, arthritis, erythema nodosum, pyoderma gangrenosa perforation, liver abscess, carcinoma phlebitis, iritis, deafness, splenomegaly, nephritis, psychosis, massive hemorrhage, endocarditis and kidney stones.

Surgical intervention in this disease should be limited to complications and sequelae. An individual afflicted with thrombo-ulcerative colitis presents a poor surgical risk if a surgical attempt must be made to relieve another intercurrent abdominal pathologic condition.

The end results of this infection may be devastating but it may also end in complete relief of all symptoms and signs of intestinal pathologic change. This happy result occurs frequently enough to make it urgent that a well-ordered regimen be followed without deviation by these patients for months and years.

CONNELLY, RICHARD CAMPBELL.

Colloidal Aluminum Hydroxide Therapy in Upper Gastro-Intestinal Lesions. Jour. Mich. State Med. Soc., 37:706-711, Aug., 1938.

Colloidal aluminum hydroxide serves as a buffer of hydrochloric acid and so reduces the irritating action of the gastric secretion on the injured mucosa of the stomach and duodenum. It may also inhibit digestion of a blood clot over a bleeding ulcer. The substance is fairly palatable and does not ordinarily produce nausea. Its use even over as long a period as one year seems to produce no harmful action on blood cytology or chemistry.

Colloidal aluminum hydroxide proved to be an antacid of considerable value in the treatment of twenty peptic ulcers, and it seems to possess an advantage over the alkali treatment of ulcer. The aluminum hydroxide has no laxative action, so provision must be made for this need in certain cases.

Hanes M. Fowler, Fort Wayne.

PALATABILITY PLUS PROVED CLINICAL EFFICACY

YOU gain much in patient goodwill and readiness to adhere to routine when you can prescribe medication of notable efficacy in dosage forms easier and more pleasant to take.

White's Cod Liver Oil Concentrate gives you the vitamins of time-proved cod liver oil—freed from the old-time handicap of disagreeable and superfluous fatty bulk—and available in a choice of three compact, potent, palatable dosage forms.

Result: grateful patients, easy ingestion; avoidance of nausea, regurgitation and digestive upsets.

In addition there is assurance that the product's clinical efficacy has been clearly established both by extensive literature and years of practical medical experience.

In *Liquid*, *Tablet*, or *Capsule* form, White's Cod Liver Oil Concentrate is suited to every type of patient. And its widespread professional recognition is obvious in the fact that White Laboratories are today one of the world's largest users of cod liver oil for pharmaceutical purposes. DRAGSTEDT, CARL A.

Some Pharmacological Considerations of Intestinal Obstruction. Illinois Med. Jour., 37:313-315, Oct., 1938.

Experimental evidence indicates that there can occur a transperitoneal absorption of toxic material from a strangulated bowel, and there is also evidence of the mesenteric absorption of toxic material under certain circumstances. In addition to the toxemia, the other factors suggested as operating in cases of obstruction are dehydration and loss of electrolytes from the blood, interference with the circulation, and some unexplained nervous factors.

The mechanical interference with circulation caused by severe distension is a quite important factor. The present interpretation of the beneficial effect of morphine in cases of ileus is that it is due to the indirect effect of morphine improving the circulation through the bowel by promoting tone and motility in the intestine.

Hanes M. Fowler, Fort Wayne.

GREEN, JOHN A.

(Ileus) Intestinal Obstruction. Illinois Med. Jour., 37:315-319, Oct., 1938.

Ileus is a symptom-complex characterized by pain, vomiting, tympanites and obstipation. According to Dean Lewis' classification, ileus may be divided into: mechanical ileus, as seen in carcinoma, bands, volvulus, intussusception, foreign bodies, etc.; strangulation ileus in which vessels are involved as in embolism or thrombosis; adynamic ileus in which the musculature of the bowel wall is paralyzed as in peritonitis and other acute abdominal conditions; dynamic ileus in which the musculature of the bowel wall is contracted, as in lead poisoning, and diseases of the central nervous system.

Intestinal obstruction continues to be one of the most deadly of all intestinal conditions and causes about the same mortality that it did two if not three decades ago. The mortality rate in ileus as given by different reports still varies between 40 and 70 per cent. The greatest cause of this high death rate is delay in treatment.

Ileus is a very frequent, if not the most common cause of postoperative abdominal complications. This deplorable situation can only be improved by becoming ileus conscious, which will result in earlier diagnosis, earlier recognition of the types and earlier institution of treatment. Until this takes place, and the patient, by means of popular medical education is also made to realize the danger of delay, no better end results may be expected.

Hanes M. Fowler, Fort Wayne.

ROSENBLUM, PHILIP.

Intussusception. Illinois Med. Jour., 74:309-313, Oct., 1938.

Intussusception is essentially a pediatric disease, 75 per cent of the cases occurring in infants under one year of age. The incidence in males over females is practically 2 to 1.

The most common symptoms in the acute variety are sudden onset in infants usually under one year, intermittent colicky pain, vomiting a palpable mass and blood in the stool. It is sometimes necessary to give an analgesic or anesthetic in order that the mass might be felt. Roentgen ray examination is very helpful especially in the subacute and chronic types.

The following conditions should be considered in the differential diagnosis, acute appendicitis, bleeding Meckel's diverticulum, prolapse of the rectum, dysentery, Henoch's purpura, tumors of the rectum, thrombosis of the splenic vein, and foreign bodies in the rectum.

The earlier the diagnosis the better the prognosis, and the importance of postoperative care, such as supplying fluids, is most essential.

Hanes M. Fowler, Fort Wayne.

COLEMAN, G. H. AND CAPPS, J. A.

Diverticulitis of the Colon. A preliminary report of a study of its potential role as a focus of infection in systemic disease. Ach. Path., 26-1, 207, July, 1938.

The authors give a preliminary report of 11 cases of diverticulitis associated with rheumatoid arthritis as a major complication in which detailed stool cultures gave predominant growths of *Str. haemolyticus* in 9 of the 11 cases. As a control group for comparison 1600 routine stool cultures from persons without evident diverticulae of the colon and arthritis gave 180 which were positive for *Str. haemolyticus* or 11 per cent, as opposed to 8 per cent. Furthermore with treatment of the patients which resulted in sharp reduction of the number of colonies present in the stools there was a parallel improvement noted in the condition of the arthritis.

N. W. Jones, Portland.

Colcher (Radiology, 29:615-621, 1937) suggested a number of improvements in the method of bringing out the mucosal markings of the stomach. The trick is to get the right amount of barium mixture and then to get the patient in the right position so that the various folds become visible. With this technic, popularized by Berg and others, some ulcers, previously invisible, can be discovered.

W. C. Alvarez, Rochester.

Red Cross Methods in Epidemic Control

DURING flood relief operations in the Mississippi Valley of 1937, Red Cross workers at a refugee camp in Northwestern Arkansas suddenly found themselves confronted with what gave promise of becoming an epidemic of cerebrospinal meningitis. The first case was reported February 5, two additional cases on February 7 and after that new cases were reported almost daily.

Local hospital facilities were crowded and the first 12 cases were cared for in a tent hospital. Subsequently a wooden barracks with three wards and a diet kitchen, of which a portion was screened off for records, supplies and scrubbing facilities were erected. To make a long story short, the last of 36 cases was admitted March 24, the hospital was closed April 3, and the remaining two convalescing patients transferred to the local hospital.

Contributing factors which were largely responsible for keeping the threatened serious epidemic within bounds included the following, according to Dr. William DeKleine, of the American Red Cross:

Daily inspection of the camp population; early diagnosis and treatment; repeated throat cultures of patients, carriers and contacts (326 in all); prompt isolation of quarantine and continuous follow-up care of all cases. National guardsmen prevented mingling of carriers and contacts with other people.

The epidemiological studies indicated that all cases, with but two exceptions, reported from one camp at Jonesboro, could be traced directly to the first patient. Most contacts occurred at camp, some in transit to the camp. Complete separation of carriers, contacts and patients until they can no longer transmit the disease, is highly important, according to the report. In Dr. DeKleine's opinion it is better to keep a few doubtful carriers in quarantine than to permit a single case to run at large. During the quarantine period treatment should be given.

Work of the Red Cross is dependent upon support from its individual members. Their dues finance its activities. The annual Roll Call for members for the coming year will begin Armistice Day and end Thanksgiving.

What Price Babies?

Baby prams, diapers, clothes, cribs and other infant needs put a dent in the average family's pocketbook. Where the mother requires a blood pick-up during or after pregnancy, economy should be a major consideration when you prescribe a hematopoietic.

Chappel **LIV-IRN**

Capsules, Tablets or Liquid

are not only absolutely dependable for prophylaxis and treatment of secondary anemias, but *they actually cost one-third less* than other good standard red cell and hemoglobin regenerators.

All Chappel LIV-IRN products are chemically, biologically and clinically controlled, easy to take, always prepared from fresh U.S. government inspected livers.

*For All Secondary Anemias Count on
Chappel LIV-IRN For A Better Blood Count*

Interesting literature on request.

The Gastric Absorption of Phenol Red in Humans*

By

ABRAHAM PENNER, M.D., FRANKLIN HOLLANDER, Ph.D.

and

MAX SALTZMAN, B.S.

NEW YORK, NEW YORK

A DILUTION indicator in gastric analysis is a substance used in the quantitative determination of the relative amounts of test-meal and secretion present in a sample of gastric contents recovered during the course of a test-meal series. It is essential that any substance used for this purpose must not disappear from the stomach except by loss through the pylorus. Such disappearance may occur through (1) absorption by the gastric mucosa, (2) adsorption on the surface of the mucosa, or (3) chemical change of the indicator by reaction with gastric contents. In the past, phenol red has been used by several investigators with the tacit assumption that the above condition has been met. (Gorham, 1923; Bulger et al, 1928; Wilhelmj et al, 1933).

Before proceeding in our own laboratory to use phenol red as a dilution indicator, we decided to investigate the validity of this assumption. In order to avoid complicated operative procedures which might tend to confuse the results by creating unphysiological conditions, it was decided to employ a substance which is already known not to be absorbed by the stomach as a standard of reference to be quantitated parallel with the phenol red. Such a substance was found in iron alum, $\text{Fe}_2(\text{NH}_4)_2(\text{SO}_4)_4$. The introduction into the stomach of a weakly acid solution of this salt and phenol red in known concentrations makes it possible to determine whether or not the dye is lost by any mechanism other than passage through the pylorus. Since the iron is not absorbed, failure of absorption of the phenol red should result in a constant ratio of iron to phenol red concentrations in all the specimens recovered in the test-meal series. If phenol red is absorbed, this ratio should increase progressively in any single series.

Evidence on the absorption of iron by the stomach has been confused by the use of surgical procedures, resulting in the creation of abnormal conditions in the stomach and introducing unknown and uncontrollable variables (Stalkenstein, 1927; Delhougne, 1931). However, since the time of Hari (1898) and Abderhalden (1900), the majority of investigators have reported that iron was not absorbed from the stomach. All these investigators allowed solutions of an iron salt to remain in contact with the non-operated gastric mucosa of various animals for varying intervals of time and then, sacrificing the animals, used histological methods to demonstrate the presence or absence of iron in the mucosa. The observations were uniformly negative. A critical review of the subject by Tartakowsky (1903) substantiated his own negative

results obtained by the same methods. An even more extensive critical review by Lintzel (1931) twenty-eight years later led to the same conclusion.

PROCEDURE

Our experimental subjects consisted of patients with unoperated gastro-intestinal tracts. In choosing our subjects we were especially careful to include a variety of gastric and systemic pathological conditions in order to obtain data of some general applicability. The individuals were preferably ones who were accustomed to swallow the stomach tube ordinarily used in obtaining gastric test-meal series. The tube was introduced into the fasting stomach; this viscus was emptied of such contents as were present and it was then washed with 100 ml. of the test-meal described below. This was followed by the introduction through the tube of varying amounts of the same test meal. Samples of gastric contents were then withdrawn periodically in the following manner: the entire contents of the stomach were removed, mixed thoroughly, and after 15 ml. had been separated for analysis, the remainder was returned to the stomach via the tube. This process was repeated at 15 or 30 minute intervals until the stomach was empty. A special effort was made to avoid trauma and bleeding, and if any blood was noted in a sample the entire series was discarded. The quantity of the test meal originally introduced varied from 150 ml. to 400 ml. depending upon the gastric capacity and tolerance of the subject.

COMPOSITION OF THE TEST MEAL

The test meal consisted of a solution of phenol red and $\text{Fe}_2(\text{NH}_4)_2(\text{SO}_4)_4$ made up in 0.01 N H_2SO_4 . Except for one experiment, the phenol red was used in two concentrations; namely, approximately 4 and 8 mg. per cent. The iron content was uniformly in the region of 0.04 N. The test-meal was acidified in order to avoid loss of iron by hydrolysis and the precipitation of basic salts in an acid gastric contents. The concentration of H_2SO_4 was kept at 0.01 N since it was found that gastric intolerance to the test-meal may result from higher concentrations. Inasmuch as the final results were to be expressed in terms of the ratio of the concentration of iron to the concentration of phenol red, in each of a series of samples of gastric contents, the components of the test-meal were measured out in close approximation to the above values and the ratios of the samples compared with the corresponding ratio for the test-meal, used in the same experiment.

DETERMINATION OF PHENOL RED

Phenol red was determined according to the method recently described by us. (Hollander, et al, 1937).

DETERMINATION OF IRON

A slight modification of the method of Fowweather (1926) was employed. 2 ml. of the sample of gastric

*From the Laboratories of the Mount Sinai Hospital, New York City. (This work was supported in part by a grant from the Friedsam Foundation).

contents were introduced into a Pyrex test tube (200 mm. x 25 mm.) which had been previously graduated to contain 50 ml. One ml. of 36 N H_2SO_4 was added and the mixture was heated to boiling until the first dense white fumes of H_2SO_4 appeared. The solution was blackened by carbonization of the organic matter present. After cooling for one minute, one ml. of Superoxol was added slowly along the side of the tube by means of a dropper. Violent bubbling and clearing of the solution resulted. When the bubbling had practically ceased the mixture was again heated to the first appearance of dense white fumes. If, at this point, further charring occurred, one ml. of Superoxol was again added in the same manner as before; this process was repeated as often as necessary to remove all organic matter. If, however, the solution took on merely a faint yellowish-brown or amber color it was allowed to cool, since it was found that this color disappeared on cooling and left a colorless solution. Special precautions were taken to stop heating at the first appearance of the dense white fumes of H_2SO_4 , because further heating usually resulted in the appearance of a finely dispersed white precipitate which did not readily dissolve on subsequent treatment and thus introduced an appreciable error in the method. The

solution was allowed to cool to room temperature and 5 ml. of distilled water were added. This was followed by the addition of 20 ml. of 0.5 N H_2SO_4 , 2 ml. of saturated $\text{K}_2\text{S}_2\text{O}_8$ and 5 ml. of 4 N KSCN , and then by dilution to the 50 ml. mark with 0.5 N H_2SO_4 . The tube was closed with a rubber stopper, thoroughly mixed by inversion, and the solution was then compared with a suitable standard in a colorimeter.

For this standard of reference, we used an approximately 0.04 N solution of $\text{Fe}_2(\text{NH}_4)_2(\text{SO}_4)_4$. It was not necessary to know its exact concentration because all the measured concentrations were calculated relative to that of iron in the test-meal itself. Two ml. of this solution were pipetted into one of the graduated Pyrex test tubes. To this were added 20 ml. of 1.5 N H_2SO_4 , 2 ml. of saturated $\text{K}_2\text{S}_2\text{O}_8$, and 6 ml. of 4 N KSCN ; this mixture was then made up to volume with 1.5 N H_2SO_4 in the usual way. The color of this reference solution was found, by comparison with freshly prepared solutions, to undergo no change for at least one hour after it was prepared.

All determinations were done in duplicate.

For the purpose of establishing the reliability of the method, we prepared a large series of solutions of $\text{Fe}_2(\text{NH}_4)_2(\text{SO}_4)_4$ of different concentrations and made up with a variety of specimens of human gastric contents as diluent. These specimens differed widely in regard to the amounts of acid, mucus, and bile which they contained. The iron concentrations were determined in these solutions and compared with their calculated values. The results are presented in Table I. The last column of this table contains the percentage error in each determination reckoned as the difference between the calculated and observed values, divided by the calculated value itself. Of the 25 specimens listed, only 3 yielded errors of greater than ± 2 per cent, whereas 11 of the observed values were in exact agreement with the calculated. Better than this, however, as a measure of the precision of the method, is the probable error of a single determination as calculated from all 25 individual errors. The value of this statistical characteristic was found to be ± 0.62 per cent of the actual concentration, which betokens a precision entirely adequate for the present purpose.

In order to investigate the applicability of Beer's Law in this procedure, iron determinations were carried out on a series of known solutions in concentrations varying from 156 mN to 0.78 mN. The standard of reference was maintained uniformly at a concentration of 39 mN. Nevertheless the observed values were invariably in agreement with those calculated according to the straight line relationship of Beer's Law—within the limits of error of the method.

SUBJECTS

Case 1. (B. B., Series Jp5) A 42 year old male, admitted to the Medical Service of Doctor George Baehr, with a 12 year history of proven duodenal ulcer which, in the 6 months preceding admission, had led to an incomplete pyloric obstruction. There was a 12 hour "gastric retention" of 40 ounces at the time the gastric analysis was done. He subsequently had a subtotal gastric resection and the resected specimen revealed a marked "gastritis" as well as a stenosing duodenal ulcer.

Case 2. (A. C., Series Jp7) A 40 year old Puerto-Rican male, admitted with an icterus due to a cholangitis of unknown etiology to the Medical Service of Doctor George Baehr. Rehfuess test meal showed a normal acidity curve. A gastro-intestinal X-ray series showed no ab-

(1) T.M. = Test meal.

(2) The residual is the difference between the corresponding value of the ratio and its mean value.

(3) P.E. = The probable error of the mean ratio. It is calculated from the formula $P.E. = 0.6745 \sqrt{\frac{\sum d^2}{n(n-1)}}$, where $\sum d^2$ equals the sum of the squares of the residuals, and n equals the number of specimens. The values given here are expressed as per cent of the mean value.

normalities. The test was done after the subsidence of the acute phase of the disease, but with the patient still showing a slight icterus.

Case 3. (L. B., Series Jp8) A 32 year old male, admitted to the Medical Service of Doctor George Baehr with a short history of vague abdominal pain and post-prandial distress. Rehfuß test meal showed normal free and total acidity curves, and a gastro-intestinal X-ray series was negative. Psychiatric examination supported the clinical impression of a "functional" basis of the symptoms.

Case 4. (L. H., Series Jp9) A 57 year old male with a long history of constipation, flatulence, and vertigo for which he had been observed in the gastro-intestinal clinic. His hemoglobin was 96 per cent Sahli with a red blood count of 5,600,000. A Rehfuß test meal series and a histamine test demonstrated a true achlorhydria; there was also a failure to excrete neutral red. A gastro-intestinal X-ray series showed no abnormalities.

Case 5. (M. S., Series Jp10) A 71 year old male observed in the gastro-intestinal clinic with a short history of anorexia, epigastric pain and sour brash, the latter coming on two hours after meals. He presented a marked loss of weight and a severe secondary anemia. Stool guaiac was positive. Rehfuß test meal series and histamine test both showed no free acidity. A gastro-intestinal X-ray series showed a mass protruding into the cardia. This was considered indicative of a carcinoma of the stomach.

Case 6. (P. C., Series Jp11) A 45 year old white male, admitted to the Medical Service of Doctor George Baehr with a history of having had several tarry stools one year previously as well as five days before admission. His hemoglobin was 22 per cent Sahli on admission. After several weeks of hospitalization a gastro-intestinal series showed a duodenal deformity indicating a duodenal ulcer without obstruction. A Rehfuß test meal series at this time showed a free acidity of 56 units and a total acidity of 81 units. The iron-phenol red test meal was administered during the period of convalescence.

Case 7. (D. M., Series Jp12) A 22 year old Puerto Rican male, admitted to the Medical Service of Doctor B. S. Oppenheimer with an attack of severe right upper quadrant pain. A thorough diagnostic work-up failed to indicate its etiology and exploratory laparotomy revealed only some perihepatic adhesions. Gastro-intestinal and gall bladder X-ray series revealed no abnormalities. Free hydrochloric acid was present in the vomitus.

Case 8. (M. Z., Series Jp13) A 67 year old white male observed on the Medical Service of Doctor George Baehr. He presented a six year history of dyspnea, angina of effort, anorexia, loss of weight and strength. Examination revealed a cachectic individual with no significant findings aside from lenticular opacities, pallor and weakness. His hemoglobin was 54 per cent Sahli with a red blood count of 2,500,000 and a color index of 1.1. Sternal biopsy revealed a picture considered typical of pernicious anemia. Rehfuß test meal series revealed an achlorhydria which persisted after histamine injection. There was no excretion of neutral red. Gastro-intestinal X-ray series showed no abnormalities.

Case 9. (M. A., Series Jp14) A 52 year old male admitted to the Medical Service of Doctor B. S. Oppenheimer with an eight weeks history of diarrhea and post-prandial substernal burning. Examination revealed a mass in the left cervical region. His hemoglobin was 90 per cent Sahli. Stool guaiac was negative. Biopsy of the mass in the neck revealed a columnar cell carcinoma. A complete roentgenologic examination of the gastro-intestinal tract revealed no abnormalities. He gradually went downhill with progressive cachexia.

RESULTS

The results are presented in Table II. The time

interval (column 3) between introduction of the test meal and withdrawal of the last specimen in any one series varied from one to three hours, depending on the exigencies of the case. The ratio of iron concentration to phenol red concentration is given in column 6, which also includes the mean value of the ratio for each series. Column 7 contains the deviations from this mean; the probable error of the mean ratio is given in column 8 as per cent of this mean. Occasionally a specimen was lost before the analytical determinations were completed. Also, in three instances not shown in the table, the deviations were so very much greater than the probable error calculated with exclusion of this value, that the specimen was disregarded completely in the analysis of the data. The statistical criterion which determines whether or not an individual specimen may be dropped in this way is that its deviation shall be greater than 4.5 times the probable error when the latter is calculated for all the observations excepting the one in question. By gross inspection of the results it will be noted that the values of the ratio in any one series are reasonably constant. Furthermore, in only one of the nine series of determinations (Case 2, Series Jp7) does the probable error possess a value greater than 1 per cent whereas in four of the series the value is less than 0.5 per cent. From this it may be concluded that no phenol red was lost in the stomach, under the conditions which obtained in these studies, except by passage into the duodenum.

Since the evidence for the non-absorption of the iron salt is solely histological, it may be objected that this evidence is not entirely conclusive. However, the histological method used is so sensitive that it is capable of demonstrating the most minute traces of iron in the tissues; when applied to the small intestine it gives a beautiful demonstration of absorbed iron throughout the entire length of the gut. The amounts of iron demonstrable may be so small that their passage from the gastric contents into and through the mucosa would not be recognizable as a change in concentration in the iron content of the test meal when analyzed by the method we have used. Hence, for our purposes, we may conclude that there is no significant absorption of iron through the gastric mucosa.

It will be noted also, from the variety of clinical conditions present, that pathological change in the gastric mucosa or in adjacent organs does not significantly affect the constancy of the concentration ratios. Thus our observations include the following: (1) Normal gastric mucosa (Cases 3 and 7); (2) Gastric mucosa unable to secrete hydrochloric acid in the absence of pernicious anemia or gastric carcinoma, due to inability of the parietal cells to function (Case 4); (3) Gastric mucosa unable to secrete hydrochloric acid and to produce the intrinsic factor of Castle; i.e., achlorhydria associated with pernicious anemia (Case 8); (4) Gastric carcinoma in a stomach unable to secrete hydrochloric acid but able to produce the intrinsic factor (Case 5); (5) Gastric mucosa in cases of duodenal ulcer, with and without pyloric obstruction (Cases 1 and 6); (6) Gastric mucosa in the presence of hepatic disease, with and without jaundice (Cases 2 and 7); (7) Gastric mucosa in the presence of the cachexia of carcinoma (Case 9). It follows, therefore, that the phenol red is not lost (except by passage through the pylorus) from the human stomach, normal or pathological, when present in concentrations which

vary from 0.87 mg. per cent to 7.77 mg. per cent. It is to be emphasized that these procedures were done under conditions as nearly "physiological" as possible and without operative trauma which might interfere with the functional activity of the gastric mucosa.

SUMMARY AND CONCLUSIONS

By the use of a known non-absorbable reference standard (ferric ammonium sulphate) it has been demonstrated that the substance, phenol red, is not absorbed from the human stomach, whether the mucous membrane is normal or altered by a wide variety of pathological processes. Furthermore, it has been demonstrated that phenol red is not altered chemically by its contact with the gastric secretions

under the conditions indicated, and that it does not preferentially stain the mucous membrane to a significant degree. In view of this it is concluded that we are justified in using phenol red as a dilution indicator in gastric analysis in humans.

A Modification of the Anson and Mirsky Hemoglobin Method for the Determination of Pepsin in Gastric Drainage

By

J. M. BEAZELL, M.S., M.B., C. R. SCHMIDT, M.S., M.B., A. C. IVY, Ph.D., M.D.*

and

J. FRED MONOGHAN, B.S., M.D.

PHILADELPHIA, PENNSYLVANIA

IN 1932 Anson and Mirsky (1) described a method for the determination of peptic activity in which hemoglobin was used as the protein substrate. As stated in their original publication on the method, "hemoglobin was chosen because it is easily prepared in large quantities, because it can be stored in solution for a long time without change, because it is rapidly digested, and because the rate at which it is digested by a given pepsin solution does not vary from one hemoglobin preparation to another." These qualities are not shared in toto by any other protein which has been suggested as a substrate for the estimation of peptic activity. Other proteins are not sufficiently reproducible so that results obtained with one preparation can be compared accurately with those obtained with another (2).

The method as originally described, although well suited to the needs of the enzyme chemist possessed a number of limitations which interfered with its value in the physiological or clinical study of the peptic activity of gastric drainage. Therefore, although the principles of the method have not been modified, the procedure has been altered in a number of respects. The incubation period has been lengthened in order to increase the sensitivity to gastric samples of low activity. The concentration of the hemoglobin has been increased in order to widen the range of peptic activity over which the method can be employed without it being necessary to resort to dilution of the more active samples. In addition, the unit has been changed so that when the activity is expressed as units per 100 cc. of gastric juice the values are in whole numbers. Since a number of other alterations have been introduced, the modified method will be presented in detail.

The method is based on the following principles.

When hemoglobin is incubated with pepsin under standardized conditions the amount of hemoglobin digested is an index of the activity of the pepsin. The extent of the digestion of the hemoglobin is estimated by precipitating the undigested hemoglobin with trichloroacetic acid, filtering, and determining the concentration of substances in the filtrate which give a blue color with phenol reagent (3). The intensity of this color is proportional to the amount of digested hemoglobin. The blue color is read in a colorimeter against the blue color produced by treating a standard tyrosine solution with phenol reagent. Thus the concentration of all trichloroacetic acid soluble materials which give a blue color with phenol reagent (tyrosine, tryptophane, and cysteine) are expressed in terms of tyrosine. The reagents give a slight but significant color when the determination is carried out without the addition of pepsin, and the gastric juice contributes a small amount of material which gives a color with phenol reagent. It is therefore necessary to control each determination by assaying a heat-inactivated sample of the gastric juice under investigation. The tyrosine equivalent of the inactive sample is then subtracted from that of the active sample leaving the true value for the tyrosine produced by the peptic digestion of the hemoglobin.

One unit of pepsin has been defined as that quantity which, acting at optimum concentration on 5 cc. of a four per cent solution of hemoglobin at a temperature of 37° C., will liberate each minute a quantity of trichloroacetic acid soluble material equivalent to one mgm. of tyrosine. At the optimum concentration the maximum digestion per unit weight of enzyme occurs, and the extent of the digestion is proportional to the concentration of the enzyme. This requirement is observed only when the enzyme is acting in low concentrations. As the concentration is increased the ratio

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago.

of digestion to enzyme concentration becomes progressively smaller. In order to obviate the need for assaying every unknown enzyme solution in a series of dilutions in order to determine the optimum concentration and thus the activity, a curve has been prepared in which the tyrosine produced by the digestion is plotted against the units of activity (*vide infra*).

Preparation of reagents: The hemoglobin solution is prepared as described by Anson and Mirsky (1).^{*} The concentration of the final solution is determined by the Kjeldahl method, the nitrogen content of hemoglobin being 17.7%. This solution is then diluted with distilled water so that the final concentration of hemoglobin is 10 per cent. The working substrate is made up as needed by diluting two parts of the 10 per cent hemoglobin with three parts of N/8 hydrochloric acid.

The tyrosine standard is made up to contain 0.15 mgm. per cc. Thrice crystallized tyrosine should be used. The solution should contain 0.5 per cent formaldehyde as a preservative, and should be stored in the ice box when not in use. The other reagents used are: 4% trichloroacetic acid; N/10 hydrochloric acid; 3.85 N. sodium hydroxide, and Phenol reagent (3).

METHOD

Two test tubes containing 5 cc. each of acid hemoglobin solution are placed in a constant temperature water bath set at 37° C. When the contents of the tubes has assumed the temperature of the bath (about 15 minutes) 1 cc. of the undiluted gastric drainage is added to one of the tubes (Ostwald pipette). To the other is added 1 cc. of a sample of the same gastric juice which has been inactivated by heating in a boiling water bath for 5 minutes. In each case the gastric juice is mixed with the hemoglobin immediately after the addition by means of a whirling motion. Exactly 15 minutes after the middle of the pipetting period the undigested hemoglobin is precipitated by the addition of 10 cc. of 4 per cent trichloroacetic acid from another test tube. Thorough mixing of the digestion mixture and trichloroacetic acid is achieved by pouring the contents back and forth between the two tubes. The material is then filtered and 3 cc. of each filtrate is transferred to an Erlenmeyer flask. To the filtrate from the sample incubated with inactivated gastric juice is added 1 cc. of the standard tyrosine solution and 19 cc. of distilled water. The 1 cc. of standard tyrosine solution is added merely to increase the subsequently developed blue color to a readable intensity. To the filtrate from the sample incubated with active gastric juice is added 20 cc. of distilled water. A series of 5 standards containing 0.15, 0.30, 0.45, 0.75 and 1.05 mgm. of tyrosine respectively is made up by adding the appropriate volume of the tyrosine standard to Erlenmeyer flasks containing 3 cc. of N/10 hydrochloric acid each. The volume of each of the standards is then made up to 23 cc. with distilled water. To each of the flasks, standards and unknown alike, is added 1 cc. of 3.85 N sodium hydroxide followed by 1 cc. of phenol reagent. After 15 minutes, during which time the blue color reaches maximum intensity, the unknown solutions are read against the standard solutions which they most closely approximate. The standard is set at 20 in the colorimeter.

In practice a large number of samples can conveni-

^{*}In order to be sure that the final hemoglobin solution is at least 10 per cent, it is advisable to employ slightly less than an equal quantity of water when taking the corpuscles i. e. four parts of water to 3 parts of corpuscular suspension.

ently be assayed at one time by adding the gastric samples to a series of tubes containing hemoglobin at 30 second intervals and then, 15 minutes from the time the first sample was added, inactivating in the same order and at the same intervals by the addition of the trichloroacetic acid. In this manner we have assayed 20 unknown samples without confusion.

The quantity of tyrosine produced by the digestion of the hemoglobin is calculated according to the following formula:

$$\left[\frac{20 \times Sa}{Ua} - \frac{(20 \times Sb - 0.15)}{Ub} \right] \times 16/3$$

in which: Sa equals the mgm. of tyrosine in the standard against which the active unknown was read,

Sb equals the mgm. of tyrosine in the standard against which the inactive (boiled) unknown was read,

Ua equals the colorimeter reading of the active unknown, and

Ub equals the colorimeter reading of the inactive unknown.

The factor 16/3 is introduced to obtain the amount of tyrosine in the total quantity of digestion mixture.

This value is then converted into pepsin units per cc. of enzyme solution assayed by means of the curve (Fig. 1) mentioned above.

The curve was prepared in the following manner. The standard method was employed in determining the quantity of tyrosine liberated by a pepsin preparation of unknown potency acting in a wide range of concentrations. From these data a curve was prepared by plotting the tyrosine liberated against the quantity of enzyme. As would be expected, after a certain enzyme concentration had been reached, the digestion was carried to completion so that higher concentrations exerted no further effect. Conversely, in very low dilutions the extent of the digestion was so slight that it was not accurately measurable. Thus, it was possible to determine the range of enzyme concentration over which the method could be employed. The curve was then refined by determining the quantity of

tyrosine produced by the same enzyme preparation acting in concentrations within the narrowed range. From the part of the curve representing optimum enzyme concentration (i.e. the beginning of the curve where the quantity of tyrosine is proportional to the quantity of enzyme) the activity of the pepsin preparation was calculated. Then, having standardized the pepsin preparation in terms of units of peptic activity per unit weight, the values on the curve were expressed as units of activity rather than weight of enzyme preparation. Obviously, any pepsin preparation could have been employed in preparing the curve. In essence, the entire procedure is designed to standardize a given pepsin preparation and then to determine the quantity of tyrosine liberated by graded quantities when assayed according to the standard procedure. Since the value of the method depends to a large extent on the reproducibility of the hemoglobin, the curve herein presented should be universally applicable, providing, of course, that proper precautions are observed in the preparation of the hemoglobin solution.

The method becomes too insensitive to give accurate results when the activity of the sample analyzed is such that the quantity of tyrosine produced is greater than the maximum shown on the curve. Therefore it is necessary to appropriately dilute such specimens and repeat the determination. Conversely, when the quantity of tyrosine is so low that it cannot be read against the most dilute standard the determination should be repeated using a 30 minute rather than a 15 minute incubation period. Since doubling the incubation period is equivalent to doubling the quantity of enzyme, these tyrosine values can be converted to

pepsin units by means of the curve, by dividing the value obtained from the curve by two.

We believe that this is a method which after a little practice can be employed by the ordinary, trained laboratory technician and which will yield standard values, expressed as units, for the pepsin content of gastric drainage analyzed in different laboratories. This claim is made on the basis of the fact, originally observed by Anson and Mirsky (1), that the substrate hemoglobin is reproducible, a fact that we have confirmed and which after much experience have found not to be true for Mett's tubes, gelatin films, edestin, casein, etc. The next best method we have found is to determine the N. P. N. on the trichloroacetic filtrate after digesting a standard casein. This method is much more laborious and time consuming than the Anson and Mirsky method as adapted by us for assaying the concentration of pepsin in gastric juice.

COMMENTS

The sensitivity of the method is demonstrated by the results shown in Fig. 1 in which it is seen that the experimentally determined values yield a smooth curve with none of the points varying significantly from the general trend.

The preparation of the reagents, particularly the hemoglobin, is time consuming. However, the permanency and reproducibility of the final preparation, plus the simplicity and accuracy of the assay method, more than compensate for the time expended.

Diabetes Mellitus and Peptic Ulcer

A Clinical Study of Nine Cases*

By

ROBERT E. ROTHENBERG, M.D.

and

IRA TEICHER, M.D.

BROOKLYN, NEW YORK

THE coexistence of two diseases in an individual offers considerable material for intensive study and presents many problems for investigation. It is important to correlate the clinical and laboratory data, and to follow the course of each disease in order to determine whether any atypical features are present. Alterations in physiology produced by one disease may be significant factors in increasing or decreasing the patient's susceptibility toward development of the second disease. The clinician not infrequently finds that the usual therapy for one lesion must be modified because of complications introduced by the presence of the second disease.

In this study, the coexistence of peptic ulcer and diabetes mellitus has been investigated and is herewith reported. According to the reports of Landé (1), Dibold (2), Lesser (3), Holcomb (4) and Falta (5), cases of this type are encountered infrequently. In 1933, Dibold studied a series of 800 diabetic patients

and found peptic ulcer in only 7 of them. Landé's series of 2,100 diabetic patients included 22 with ulcer, whereas Falta found none with peptic ulcer in a group of 1,403 cases. During 1934 and 1935, there were 2,569 patients with diabetes admitted to Joslin's (6) clinic, among whom there were but 13 patients suffering from peptic ulcer.

The present study is based on all cases of diabetes mellitus and peptic ulcer admitted to the hospital from January, 1913, to August, 1936. During this period there were 130,500 hospital patients, of whom 3,525, or 2.7 per cent, had diabetes. Of this number of diabetic patients, only 9, or 0.25 per cent, had a coexisting peptic ulcer. There were 1,952 patients with proved peptic ulcer admitted during this time, constituting 1.49 per cent of all hospital admissions. Thus, the incidence of ulcer in the total of 130,500 patients was 1.49 per cent as compared with an incidence of 0.25 per cent in the 3,525 diabetic patients. Similarly, diabetes occurred in 2.7 per cent of the total number of hospital

*Jewish Hospital of Brooklyn, Medical and Surgical Services.

admissions, but in only 0.46 per cent of those patients with peptic ulcer. Table I. Portis and Jaffé (7) in necropsy studies on 339 cases of peptic ulcer found that diabetes was an associated pathologic condition

TABLE I

1913—1936	Total Hospital Admissions	130,500
1913—1936	Total Number of Diabetic Patients	3,625 — 2.7 per cent of total admissions.
1913—1936	Total Number of Ulcer and Diabetes	9 — 0.25 per cent of total diabetic patients.
1913—1936	Total Number of Peptic Ulcer Patients	1,952 — 1.49 per cent of total admissions.
1913—1936	Total Number of Ulcer and Diabetes	9 — 0.46 per cent of total peptic ulcer patients.

in but one case, constituting an incidence of approximately 0.3 per cent.

It would appear from the above statistics that people with diabetes mellitus, susceptible as they are to numerous medical and surgical complications, possess increased resistance to the formation of peptic ulcer. When our figures are added to those of the aforementioned authors, it is seen that there were but 51 cases of peptic ulcer in a total of 10,397 diabetic patients, or an incidence of 0.49 per cent. Table II.

In our group there were 6 females and 3 males. To evaluate these figures, it must be borne in mind that these two diseases have opposite predispositions for sex, namely, diabetes in females and peptic ulcers in males. Obviously, an indication of sex incidence can scarcely be obtained from such a small number of cases. In 6 patients the diabetes was known prior to the diagnosis of ulcer, while in the other 3 the ulcer apparently antedated the onset of the diabetes.

When the clinical picture of the average patient with peptic ulcer was compared with those having ulcer plus diabetes, several atypical features were noted. Patients with peptic ulcer usually have a definite association between food and pain, but in only 1 of our 9 patients did such a relationship exist. Relief of pain following intake of food is frequently found in the average case of ulcer, yet only 1 patient in our series gave such a history. Furthermore, but 2 of 9 patients told of having experienced relief of symptoms

TABLE II

	Number of Diabetic Patients	Number with Co-existing Ulcer	Incidence, Per Cent
Dibold	500	7	0.87
Landé	2,100	22	1.04
Falka	1,403	0	0.00
Joslin	2,550	13	0.50
Rathenberg & Teicher	3,625	9	0.25
TOTAL	10,397	51	0.49

following the intake of alkali medication. Although gastro-intestinal symptoms were the complaints for which all 9 patients sought hospital admission, their presenting histories and findings were not clearly defined. The diagnosis of peptic ulcer was made on admission in only 5 of the 9 cases. The remaining 4 patients entered the hospital with diagnoses of gall bladder disease in two, chronic constipation in one, and hepatic cirrhosis in the fourth patient.

The ulcers were located in the duodenum in 7 patients, on the lesser curvature of the stomach in one, and in the pylorus and duodenum in another.

Gastric analysis was performed in 7 of the 9 cases and hyperacidity was present in only 1 case. Five patients had normal acidity, 1 had subacidity, and the other had hyperacidity. It is interesting to note that the patient with hyperchlorhydria had no free hydrochloric acid in the fasting specimen.

The diabetic status of the patients was mild, and control was maintained without difficulty. This is evidenced by the fact that the complaints for which they sought hospital admission were related to stomach symptoms in all of the nine cases. Only three patients required daily insulin injections. Blood sugar levels were below 150 milligrams per 100 cc. in 4 cases, between 150 and 200 milligrams in 2, and above 200 milligrams in 3 cases. Complaints of polydipsia were elicited from 5 patients, polyuria was present in 4, and polyphagia was not reported in any of the 9 patients.

Six of the 9 patients were treated medically, and in this group greatest improvement was noted when the hospital diet was directed toward treatment of the ulcer rather than the diabetes. Three of these 6 left the hospital greatly improved on a Sippy diet regime. The other 3 medically treated patients were given diets for their diabetes, and left the hospital unimproved. Gastrojejunostomy was performed on 3 of the 9 patients. Of these, one made an uneventful recovery and was discharged free of complaints; one patient, aged 72 years, died of a cardiac collapse on the seventh post operative day; and the third, aged 65 years, died of uremia on the eighth post operative day. Table III.

COMMENT

Studies of gastric extractions after the usual Ewald meal in diabetic patients reveal a low acidity in a large proportion of cases. Wiechman (8) investigated 124 patients and found anacidity in 31, or 25 per cent of the total, subacidity in 18, or 15 per cent of the cases, normal acidity in 46, or 37 per cent of the series, and hyperacidity in 29, or 23 per cent of the total number. Thus, 40 per cent of his diabetic patients had a low gastric acidity, whereas in a group of normal people of corresponding age only 10 per cent would ordinarily show a hypochlorhydria or achlorhydria. Root (9) and Bowen and Aaron (10) also state that gastric acidity is decreased in diabetes. Dibold, Lesser and Lampé (11) point out that the degree of gastric acidity is affected by the level of the blood sugar and the use of insulin. Dibold stated that low acidity is usually found in the presence of high blood sugar, and conversely, high gastric acidity is brought about by hypoglycemia. He illustrated the effect of insulin in increasing gastric acidity and incidentally motility, by performing analyses of the stomach content of a diabetic patient over a twenty-four hour period. He found that the fasting specimen prior to administration of insulin contained

no free hydrochloric acid whereas, following the injection of insulin, free hydrochloric acid appeared and reached its highest level when the insulin effect was greatest. With the diminution of insulin effect on glycemia, there was a decline in the gastric acidity. Lampé emphasized the fact that in hypoglycemia, both gastric secretion and motility are increased. Thus, the diabetic patient, with diminished production of body insulin, can be made to secrete greater quantities of gastric hydrochloric acid by parenteral insulin injection. This relationship of blood sugar and insulin to the acid secreting cells of the stomach appears to be a definite one. At the present time however, it can not be stated whether gastric secretion is directly affected by the hormonal action of insulin, or by intermediate metabolic changes resulting from alteration of the blood sugar level.

The treatment of diabetes mellitus and peptic ulcer in the one individual presents many problems. High carbohydrate, low fat diabetic diets are unsatisfactory for ulcer patients and may cause activation of the gastric or duodenal lesions. It is likewise difficult to maintain an ulcer diet which will conform to diabetic requirements. We have found that results seem to be most satisfactory in those cases in which diet is directed toward treatment of the ulcer, and where the diabetic status is controlled by insulin injections whenever necessary. As previously noted, the three patients who were put on Sippy diets left the hospital improved, whereas the three patients who were receiving diabetic diets were not relieved of their gastric symptoms.

Fitz (12) and others agree that operative procedures on patients with both diabetes and peptic ulcer are undertaken with more than the usual risk. Surgery should be resorted to only after thorough medical treatment has proved ineffective and when there are indications that persistence of symptoms will endanger the life of the patient. Of the three patients in this series on whom surgical procedures were instituted,

intervention was necessitated by persistent bleeding in one case and pyloric stenosis in the other two.

A possible explanation for the infrequent occurrence of peptic ulcer in patients with diabetes mellitus may be found in studies of gastric acidity. In this series, only 1 patient in the group of 7 with records of gastric acidity gave evidence of hyperchlorhydria. In cases of proved peptic ulcer, this finding is most unusual! Furthermore, the hydrochloric acid in these seven cases of combined diabetes and ulcer averaged 53°, whereas in our cases of peptic ulcer without diabetes,* it averaged 68.1°. Root, in reporting achlorhydria in 30 to 40 per cent of diabetic patients, noted that the incidence of achlorhydria became greater with the longer duration of the diabetes as well as with the age of the patient. If, as many workers maintain, there is a definite relationship between gastric hyperacidity and formation of ulcer, then the lowered acid secretion in diabetic patients would seem to be one of the prime factors in decreasing their susceptibility to ulcer formation. However, some doubt is cast upon the lone role played by hyperchlorhydria in ulcer formation when one notes that 6 of our 9 patients developed ulcer despite the presence of diabetes for many years and despite the fact that they were found to have normal gastric acidity on hospital admission.

The possibility of failure to correctly diagnose gastro-intestinal complaints in a diabetic patient must be considered. The malnutrition and abdominal discomfort could be attributed to poor glycemic control and further diagnostic investigation be neglected. Holcomb and Dibold emphasize the point that persistent gastro-intestinal complaints in a well controlled diabetic patient requires careful exclusion of intrinsic gastric pathology as a possible causative factor. It is important to realize also that the etiology of glycosuria in a known ulcer patient must be investigated to exclude a pancreatitis as the source. Jankelson and Rudy

(13) reported three cases of peptic ulcer penetrating into the pancreas, with disappearance of the glycosuria post operatively. A type of glucose tolerance curve with a sharp rise in the first hour, followed by a return to normal within two and one-half hours, was found by van den Bergh and Von Henkelom (14) in cases of ulcer with pancreatic involvement. The simultaneous occurrence of duodenal ulcer with renal glycosuria in two brothers was reported by Meyer (15). It is apparent that when glycosuria is found in the presence of peptic ulcer, adequate medical investigation must be instituted to determine its etiology.

SUMMARY

1. In a group of 3,525 diabetic patients, peptic ulcer was present in 9 cases, constituting an incidence of 0.25 per cent. Of 130,500 total hospital admissions, 1,952 patients, or 1.49 per cent, had peptic ulcer. Both diabetes mellitus and peptic ulcer were present in 51 cases out of a group of 10,397 diabetic patients collected from reports in the literature.

2. Low gastric acidity is found in a large proportion of diabetic patients. To this fact, the infrequency of peptic ulcer in the presence of diabetes may be attributed. In 7 of our cases of peptic ulcer associated with diabetes, gastric acidity was normal in 5 patients, below normal in one, and above normal in another.

3. Ulcer symptomatology was atypical in a large proportion of the cases of coexisting diabetes mellitus and peptic ulcer. The diabetic status of these patients was mild and occasioned few symptoms.

4. Best therapeutic results were obtained in those cases of peptic ulcer and diabetes mellitus who were placed on a Sippy diet, with the diabetic status being controlled by insulin injections whenever necessary.

We are greatly indebted to Dr. Simon Rothenberg for his many helpful suggestions in the preparation of this paper.

ABSTRACTS OF CASE RECORDS

Case No. 162582, a 52 year old female, with known diabetes for past 11 years. During this period, treatment had been dietary with occasional injections of insulin. Mild polydipsia and polyuria was present. For past three years, patient noted heaviness and fullness in epigastrium $\frac{1}{2}$ to 1 hour after meals. Eighteen pounds in weight had been lost in the nine months prior to hospitalization. Blood sugar was 200 milligrams per 100 cc. and the urine showed 2.5 per cent sugar. Gastric analysis showed free hydrochloric acid of 15 degrees and total acid of 30 degrees. X-ray examination demonstrated a constant deformity of the duodenal bulb. The patient was placed on a diet containing 150 grams of Carbohydrate, 60 grams of Protein, and 50 grams of Fat, with insulin Units 10 three times daily. Diabetic status was controlled, but no marked change in subjective symptoms followed. The patient be-

came very uncooperative and was discharged from the hospital unimproved.

Case No. 169853, a 72 year old female, with known diabetes for past 4 years, which had been treated by dietary measures only. For 2 weeks prior to hospital admission she suffered from a burning and soreness in epigastrium which came on 1 to 2 hours after eating and was not relieved by alkali medication. Blood sugar was 350 milligrams per 100 cc. and urine contained 1.6 per cent sugar. The highest readings on gastric analysis were 25 degrees for free hydrochloric acid and 65 degrees for total acid. X-rays demonstrated a large ulcer on the lesser curvature of the stomach with no gastric retention at 6 hours. Patient was placed on a diet containing Carbohydrate 150 grams, Protein 60 grams, and Fat 50 grams, and was given Insulin Units 5 three times daily. The diabetes was controlled on this regime but gastric symptoms persisted. Two days before discharge from hospital, Sippy diet and powders were given; on this course the patient began to experience some relief of symptoms.

Case No. 196807, a 48 year old female with known diabetes for 9 years. No insulin had ever been taken. Mild occasional pruritis vulvae and polyuria had occurred. For the past year, patient had noted a bitter taste in mouth, and on the day before admission had noted a tarry stool. Blood sugar was 148 milligrams per 100 cc. and urine showed 0.15 per cent sugar. Glucose tolerance test showed a typical diabetic curve. Fasting gastric specimen contained free hydrochloric acid, 12 degrees, and total acid, 36 degrees. Twenty-four degrees of free hydrochloric acid and 40 degrees of total acid were found in subsequent samples. An irregular duodenal cap was shown on X-ray. The patient was put on a diet of 160 grams of carbohydrate, 60 grams of Protein and 60 grams of Fat. During hospital stay, symptoms were not relieved.

Case No. 109742, a 58 year old male, with a 24 year history of alcoholism. Diabetes was known to have been present for past 4 years and dietary regime had been advised. Upper abdominal pain, nausea and belching, coming on 2 to 3 hours after meals, had been experienced for 4 months prior to hospital admission. Loss of 18 pounds in weight during this period. Examination revealed a smooth liver enlarged to level of umbilicus. Blood sugar was 100 milligrams per 100 cc. and urine showed 0.9 per cent sugar. Glucose tolerance test showed typical diabetic curve. Gastric analysis contained 18 degrees free hydrochloric acid and 47 degrees total acid. X-ray showed deformed duodenal cap and marked 6 hours gastric retention. On a Sippy diet the patient improved and was discharged from the hospital. He returned 2 years later because of recurrence of pain and daily vomiting. At operation, a large duodenal ulcer was found and a gastroenterostomy was performed. Postoperative course was uneventful, diabetes was controlled without insulin, and the patient was discharged from hospital free of complaints on a Lanhartz diet.

Case No. 140182, a 72 year old female with a known diabetes past 11 years, which was controlled by diet, and occasioned only mild polyuria and polydipsia. Epigastric pain present for four weeks before hospitalization. On admission, there was slight epigastric tenderness. Blood sugar was 130 milligrams per 100 cc. and urine showed 0.8 per cent sugar. X-ray showed an irregular duodenal bulb. Stools contained blood. Moderate secondary anemia was present, for which a transfusion was given preoperatively. At operation, a callus ulcer involving the first and part of the second portion of the duodenum was found. Gastroenterostomy was performed. Patient died on 7th post operative day of cardiac collapse.

Case No. 120904, a 54 year old male who for past 9 years had suffered from attacks of boring epigastric pain, belching, and sour eructations occurring 3 to 4 hours after meals. Exacerbation of symptoms for 2 weeks prior to

admission and appearance of tarry stools. Patient was found to have diabetes 6 months previous to hospital admission, which was controlled by diet alone. Mild polyuria and polydipsia was noted. Blood sugar was 150 milligrams per 100 cc. and urine showed 0.1 per cent sugar. Gastric analysis was performed and the highest degrees for free hydrochloric acid were 40, and for total acid, 50 degrees. X-ray studies revealed a deformed duodenal cap. Patient improved markedly on Sippy diet with alkaline powders, and diabetes was kept under control.

Case No. 142108, a 46 year old female with history of attacks of nausea and vomiting not associated with eating, occurring at irregular intervals during the past five years. Tarry stools on one occasion two years previously. Hematemesis three days prior to hospital admission, followed by recurrence of tarry stools. Blood sugar was found to be 334 milligrams per 100 cc. and urine contained 2 per cent sugar. Hemoglobin was 45 per cent with 2,180,000 Red Blood Cells per cm. A transfusion of 500 cc. of whole blood was given and the patient was placed on a Sippy diet. Response to treatment was good and the diabetes was controlled without insulin. X-ray examination revealed an irregular duodenal cap. Patient was discharged from the hospital on a Sippy diet much improved.

Case No. 105807, a 58 year old male, with known diabetes past 15 years. Epigastric pain radiating to back, belching, frequent vomiting, usually occurring 2 to 3 hours after meals, had been present for past 6 months. Sippy diet and daily doses of insulin had resulted in moderate relief of symptoms until four weeks before hospitalization when he experienced daily attacks of pain. On admission, the state of nutrition was poor. Moderate tenderness was elicited in right upper quadrant of abdomen. Blood sugar

was 176 milligrams per 100 cc. and urine contained 3 per cent sugar and 4 plus acetone. Analysis of vomitus revealed 36 degrees of free hydrochloric acid and 59 degrees of total acid. X-ray examination showed an irregular duodenal bulb and slight 6 hour gastric retention. Diabetes was controlled by three daily injections of 10 Units of insulin, and he showed rapid improvement of ulcer symptoms with Sippy diet and alkaline powders.

Case No. 141212, a 64 year old female, with known diabetes for the past ten years. Attacks of right upper quadrant abdominal pain that radiated to right shoulder, nausea and vomiting during past nine years. These episodes were unrelated to food ingestion. Exacerbation of symptoms during past four months caused patient to seek hospital admission. Physical examination revealed slight epigastric tenderness. Blood sugar was 208 milligrams per 100 cc. Gastric analysis showed a free hydrochloric acid of 48 degrees and a total acid of 80 degrees. A deformed duodenal bulb and marked 6 hour gastric retention was found on X-ray examination. Patient improved on a Sippy diet and was discharged from hospital. She returned nine months later because of recurrence of abdominal pain and vomiting. At operation, a stenosing duodenal ulcer pointing toward the pancreas was found. Gastroenterostomy was performed. For six days the post-operative course was fair and a mild glycosuria was controlled without insulin. However, for the next twenty days she vomited with increasing frequency and the blood sugar rose to 333 milligrams per 100 cc. Because of persistent vomiting, a laparotomy was performed and many adhesions in the region of the anastomosis were liberated. Post-operative reaction was poor, and the blood urea nitrogen, which had been normal, rose to 55.5 milligrams per 100 cc. The patient expired three days after the second operation.

End Results After Gall Bladder Operations With an Analysis of the Causes of Residual Symptoms*

By

S. G. MEYERS, M.D., D. J. SANDWEISS, M.D.

and

H. C. SALTZSTEIN, M.D.

PATIENTS who have had biliary tract operations present themselves so frequently with abdominal complaints that they challenge the diagnostic and therapeutic resources of the physician. We undertook this study:

I. To ascertain what benefit was derived from biliary tract surgery insofar as preoperative symptoms were concerned.

II. To determine the causes of failure if biliary symptoms persisted.

III. To determine what conditions caused abdominal distress mimicking biliary symptoms before and after biliary tract surgery.

IV. To study the incidence of those diseases most commonly associated with biliary tract infections.

SELECTION OF MATERIAL

The 165 patients (Table I) reported by us represents all those we have encountered in the last eight years who were operated for biliary symptoms and

who could be adequately studied postoperatively. 199 operations were performed. Eighty-four operations (42%) were performed while under our care, the remainder were performed by others. All patients were personally studied by us. No written questionnaires were used. The patients were thus available for quizzing, physical, laboratory and X-ray examinations. A

patient might appear for an unrelated complaint, as an acute upper respiratory tract infection, but if she had had a gall bladder operation, data were obtained relative to the type of operation, symptomatic relief, etc.

Thirty-one per cent of the patients were seen in

clinic practice, the remainder in private practice. Eighty-two per cent of our patients were Jewish. There were no colored patients, although the incidence of colored patients admitted to our clinic is 26%.

RESULTS OF CHOLECYSTECTOMY

The average period of follow-up study was 7½ years. Thirty-eight per cent were followed ten years or more (Table II). We attach importance to this lengthy post-operative observation since the longer these patients are followed the more postoperative biliary symptoms are found.

Results in 136 cholecystectomies are classified as good, fair (improved) and poor (Table III).

It has been repeatedly pointed out that there is a marked discrepancy between the end results in cholecystitis with stones and in the stoneless gall bladder. Our series bears this out.

CHOLECYSTITIS WITH STONES

Cholecystectomy was performed in 102 patients who were found at the operating table to have stones (Table III). In seventy per cent the results were good, with subsidence of all or almost all of symptoms. In thirteen per cent the results were fair. Among the fair results there was one group in whom colic recurred with such frequency and severity that further surgery was considered, but the colic finally disappeared. In a second group colic subsided but there was residual indigestion of a biliary character which persisted over long periods. This indigestion was somewhat difficult to control. Thus eighty-three per cent benefited from the operation. In 17 patients (17%) the results were poor, colic persisting or recurring following cholecystectomy. Most of these patients were re-operated. Stones were found either in the stump of the gall bladder (1), cystic duct (2), or common duct (8). A thickened common duct (chronic cholangitis) without stones was drained for a long period in one patient. Operation revealed adhesions partly obstructing a loop of bowel in two patients. A clinical diagnosis of biliary tract infection was made in two patients and biliary dyskinesia in an additional patient.

STONELESS GALL BLADDER

Cholecystectomy was performed in 34 patients who were found at the operating table to have no stones (Table III). In 12 patients (35%) the results were good. An additional 2 patients (6%) had fair results,

making a total of forty-one percent who improved after operation.

Of the twenty patients who did not benefit from cholecystectomy for stoneless gall bladder, the subse-

TOTAL	<u>102</u>	<u>34</u>

quent course suggests that nine perhaps should not have been operated. They were subsequently found to have extra-biliary conditions as neurosis, gastro-intestinal allergy, endocrinopathy, pelvic tuberculosis, etc. In the opinion of some, these nine patients should be excluded from a survey of end results and should be charged off as errors in diagnosis. We cannot agree with this standpoint. Although in retrospect there may have been a questionable indication for operation, decision to operate was based on the condition that presented itself at that time. We studied some of these patients for several years and surgery was finally resorted to after most careful deliberation. The group

in whom the postoperative course suggests poor selection of cases for operation will continue to be a problem for the practitioner and will contribute to the high incidence of poor results in gall bladder surgery.

The causes of failure in the remaining eleven were biliary in nature: thickened common duct (chronic cholangitis) (1); probable cholangitis (2); post-operative adhesions (1); persistent colic and indigestion of biliary origin (5); and persistent colic and indigestion of undetermined origin (biliary dyskinesia) (2).

PROGNOSIS FOR RELIEF FROM OPERATION

Improvement after cholecystectomy for stones being about twice as frequent as in the stoneless cases it is necessary to bear in mind that the presence or absence of stones in any particular case may be unpredictable. The decision to operate is made on the basis of clinical symptoms the most important of which is colic. In 119 patients where colic was present pre-operatively seventy-six per cent were benefited by the operation. In the 17 patients where no colic was present, only forty-one per cent benefited from the operation. Where no pre-operative colic was present and no stones found at operation, surgery was almost uniformly unsuccessful, ten of eleven cases receiving no benefit. This latter group constitutes the worst group from a prognostic standpoint.

Graham and Mackey (1) point to the frequency of errors in diagnosis as a cause of failure to relieve the patient's symptoms. They point out that many common conditions are often confused with gall bladder disease, particularly with the less severe forms of cholecystitis. Errors in diagnosis contribute a considerable proportion of failures in stoneless gall bladder.

COMPARATIVE FIGURES ON END RESULTS

Others (2, 3, 4, 5, 6)* have reported good results from cholecystectomy in calculous cholecystitis averaging 80%-85%.* Our end results (83% benefited) is in agreement with the prevailing opinion here.

In non-calculous cholecystitis, however, there is decided disagreement in the percentage of relief to be expected (1, 2, 3, 4, 6, 7, 8, 9, 10). Figures vary from 85% to 53%,* the latter quoted by Stanton (10). The reports of Cattell (8), Graham and Mackey (1), Maynard (4), Wilkinson (9) and Wilson, Lehman and Goodwin (6), are all in the neighborhood of 65% benefited. Our series (41% benefited) is the lowest we have encountered thus far.

II

CAUSES OF RECURRENT SYMPTOMS OF BILIARY TRACT ORIGIN

1. *Common Duct Stones* were present in 8 cases. In a few the common duct stone was probably present but was overlooked at the time of the cholecystectomy. In others stones formed in the biliary tree after cholecystectomy. For instance one of our patients had cholecystectomy with removal of stones, no stones being palpated in the common duct. Colic recurred and 3 months after the cholecystectomy the common duct was opened, stones removed, and a T tube inserted.

*All figures quoted, including ours, refers to the percentage benefited among the surviving patients. As our series was composed of patients studied clinically an average of 7½ years post-operative, we have excluded post-operative deaths and untraced cases from the figures quoted in Articles 1 to 11 inclusive. Inclusion of the patients who died would decrease the percentage benefited by as much as 5%.

Three years later a third operation was performed for recurrent colic and stones were again removed from the common duct. Colics have recurred since the third operation and re-operation has been advised. This is a pronounced example of a "stone-former" or stone diathesis.

2. *Cystic Duct Stone* caused recurrent colic in 2 cases. There were two additional instances in which a stump of the gall bladder was found at the secondary operation. In one of these latter there had been a re-formation of stones.

3. *Thickened Common Duct (Chronic Cholangitis)*: In two patients who had frequent and severe recurring colics after cholecystectomy, secondary operation disclosed a thickened common duct but no stones. The common duct was thickened probably because of chronic cholangitis. Prolonged T tube drainage permanently relieved one patient and gave only temporary relief to another.

4. *Residual Biliary Indigestion (Residual Biliary Tract Infection?)*: Residual indigestion, biliary in type was present in 29 patients (21%) after cholecystectomy. These are listed in Table III (Good results, item 5: Fair results, item 2). Distress was confined to the epigastrium and came immediately after meals with belching, distension, food selection, and idiosyncrasy to fatty foods. The distress was similar to that present pre-operatively between attacks of colic. There was incomplete relief from bowel management, although some of these patients were constipated. Duodenal drainage was done on a number of these patients to determine the presence of cholesterol crystals, calcium bilirubin pigment, bile stained pus cells, etc. Flat plate studies of the bile passages and gastrointestinal studies were done. The patients were observed for icterus by clinical and chemical methods, and for fever and leukocytosis. None of these examinations gave diagnostic information as to the cause of the indigestion in this group of patients. It is our opinion, however, that this residual indigestion is due to infection in the biliary tree or the sequelae of infection, resulting in malfunction of the bile ducts, liver or pancreas.

Various theories have been proposed to explain this group of symptoms:

(a) Hepatitis. Ravdin Riegel Johnston and Morrison (11) have demonstrated that diminution of bile salts occurs with biliary tract disease. In the hepatitis of biliary tract disease of long standing the bile salts, which play such an important role in the activation of lipase and in the digestion and absorption of fats are definitely reduced in concentration. Agrifoglio (12) demonstrated a decreased utilization of fats, chiefly soaps and fatty acids in the cholecystectomized dog. This decrease appeared within 90 days. After 10-15 months the utilization of fats except soaps improved. This corresponds to the clinical picture in humans, in whom post-operative indigestion finally clears up.

(b) Cholangitis (Scott (13)). (c) Biliary Stasis (Green, Twiss, Carter (14)) (Brown and Dolkart (15)). (d) Spastic biliary tract (Kunath (3)). (e) The gastric catarrh which may be present in a progressing cholecystitis may persist after cholecystectomy (Deaver and Bortz (2)). (f) Spastic or irritable colon (Wilkinson (9)). (g) Biliary Dyskinesia.

5. *Biliary Dyskinesia*: A recent concept is that motor disorders of the extrahepatic biliary passages may produce the symptoms of gall bladder distress or

colic in the absence of stone or inflammation. The historical development and physiologic basis for this so-called biliary dyskinesia has been recently summarized by Ivy and Sandblom (16). They suggest that the presence of an irritable or hypertrophied sphincter of the common duct may explain the recurrence of symptoms in some patients following cholecystectomy.

Biliary colic occurs not infrequently soon after cholecystectomy, resulting in the so-called convalescent colic. The loss of the reservoir function of the gall bladder causes compensatory dilatation of the larger bile ducts and there is derangement of the emptying mechanism. McGowan, Butsch and Walters (17) measured the common duct pressures post-operatively and demonstrated a rise in the intraductal pressure during these attacks of colic. Following the inhalation of amyl nitrite the pressure fell and the colic was relieved. These colics, coming on during the first six months of the post-operative period, frequently are a source of worry. If the common duct has not been opened at the time of operation, one should think of convalescent colic as well as over-looked stone. Differential diagnosis between convalescent colic and common duct stone can sometimes be made on the fact that with stone there may be fever, leucocytosis or icterus. A flat plat of the abdomen may be of value. Duodenal drainage may reveal calcium bilirubin pigment or cholesterolin crystals. In some cases it is impossible to differentiate the two conditions. Re-operation must not be hastily done. If the attacks of colic are infrequent and not severe it is advisable to postpone operation for as long as a year. Several of our patients had subsidence of colic within this length of time. Weir and Snell (18) state that these post-operative or "convalescent" colics are usually less severe than the pre-operative colic, that they become progressively less painful, and finally clear up. When the attacks persist and the patients are re-operated and no stones are found, Judd (19) advocates prolonged drainage of the common duct with a T tube. This gives symptomatic relief.

Two of our cases of recurrent colic of undetermined origin were thought to be due to biliary dyskinesia occasioned by the activity of a duodenal ulcer. Both of these patients had the gall bladder removed for cholecystitis. In one, stone was present; in the other it was absent. Duodenal ulcer was later demonstrated by X-ray in both instances. On ulcer management there was subsidence of colic with occasional recurrence of ulcer indigestion.

That biliary dyskinesia can also be due to disorders of the sympathetic nervous system has been suggested by Weir and Snell (18). For instance, one of our patients, intensely neurotic, had removal of gall stones without removal of the gall bladder. Later there was recurrence of colic of such a nature that at times it was difficult to determine if the attack was organic or functional in origin. A chronically infected gall bladder without stones was removed. The severe colic persisted. Careful re-examination including two hospital admissions failed to reveal evidence of common duct stone. She has an intense anxiety neurosis and recurrent colics are related to domestic difficulties.

The concept of biliary dyskinesia is necessary to explain recurrent severe biliary colic in several of our patients who had no demonstrable evidence of calculus or inflammation in the biliary tree. Biliary dyskinesia may be looked upon as a functional disturbance due to

spasm of the sphincter of Oddi which may result from cholecystectomy, duodenal ulcer or neurosis.

III

EXTRA-BILIARY CAUSES FOR SYMPTOMS AFTER CHOLECYSTECTOMY

Residual symptoms after gall bladder operations may be due to several causes not related to the biliary tract:

1. *Intestinal adhesions* with partial intestinal obstruction was the cause of recurrent attacks of colic in only two of our cases and of recurrent indigestion in an additional one. In the two cases with colic the pre-operative diagnosis was common duct stone. No stones were found at operation. Adhesions obstructing a loop of small bowel were freed with complete relief of symptoms. The case with indigestion persisting after cholecystectomy was re-operated six years later and a patent common duct, without stones was found. Adhesions, however, were separated, since which time she has had symptomatic relief. Intestinal adhesions are often blamed for recurrent pains following cholecystectomy, but are usually an inadequate or incorrect explanation of the symptoms. Adhesions cause symptoms if the bowel is obstructed or there is interference with the motility of the intestinal tract. All in all, one must be very cautious in ascribing a colic to postoperative adhesions.

2. *Spastic Colon Associated with Biliary Tract Disease:* Spastic colon was noted in 46% of our cholecystectomized patients. Table III lists only 8 cases (6%) as having spastic colon. When more important residual symptoms were present, the added presence of spastic colon is not noted in the table. Rehfuess and Nelson (20) report an incidence of 75% of spastic constipation in gall bladder disease.

In many patients spastic colon caused epigastric indigestion which could be easily confused with that of biliary origin. It is important to recognize that spastic colon may mimic biliary tract disorders. The similarity in symptoms of chronic cholecystitis and irritable colon has been pointed out by Wilkinson (9). Epigastric distress, gas, belching, pain in the upper abdomen, and constipation are present in both conditions. Even cholecystography will not distinguish between these two diseases as Lahey and Jordon (21) have shown that 44% of the patients with chronic dyspepsia whose gall bladder cannot be visualized after the administration of dye will later show normal filling after an adequate period of bowel management.

Bowel management, with bland diet, antispasmodics as belladonna, sedatives as phenobarital or bromide, local heat, and use of hot water or mineral oil or oil enemata will often clear up indigestion in a cholecystectomized patient.

3. *Peptic Ulcer:* In the cholecystectomized group of 136 patients, 15 had duodenal ulcer, an incidence of 11%. In addition 7 cases (5%) had a clinical diagnosis of peptic ulcer, although no ulcer was demonstrated roentgenographically. These patients had typical post-prandial distress, complete relief with ulcer management and recurrences from time to time.

Of the 15 definitely proved ulcer patients the ulcer was known to be present previous to cholecystectomy in 3. At operation two had calculous cholecystitis and one non-calculous cholecystitis.

In 10 patients indigestion persisted after cholecystectomy. The cause for this was later demonstrated to

be due to ulcer. Four of these patients were found at operation to have calculous cholecystitis, the remaining 6 non-calculous cholecystitis.

In the remaining 2 patients all gastro-intestinal symptoms disappeared following cholecystectomy. However, 1 and 9 years after the cholecystectomy indigestion recurred which was demonstrated to be due to ulcer. One had calculous cholecystitis and one non-calculous cholecystitis.

To summarize the 15 patients with ulcer, 7 had calculous cholecystitis and 8 non-calculous cholecystitis.

Laird (22) reports an incidence of 4.8% of peptic ulcer in 250 consecutive patients who underwent cholecystectomy. He points out that the incidence of ulcer with cholecystitis is not markedly higher than the percentage of ulcer found in the general population and concluded there is no close inter-relationship between the two diseases. McVicar and Wer (23) found the two diseases associated in 4.1%. Bruce (24) found an incidence of 6% in 100 consecutive cases and he concludes the coexistence of cholecystitis and duodenal ulcer is not rare. He advocates a careful examination of the duodenum when operating for gall bladder disease. Judd (25) emphasized the importance of cholecystitis in bleeding duodenal ulcer.

The incidence of 11% of ulcer in our series of cholecystitis is considerably higher than reported by others. The high incidence is possibly due to the following factors:

a. Our figures include not only the ulcers found at the cholecystectomy but also those that developed during a follow-up period averaging seven and one-half years.

b. There may be a common focus of infection in the portal area, or an infection of one organ may drain to the other organ via the lymphatics.

c. Mistakes in diagnosis. In the eight patients with non-calculous cholecystitis and even in the 7 calculous cases one could take the viewpoint that the ulcer was a more important cause of symptoms than the gall bladder disease and that the treatment should have been directed at the ulcer rather than the gall bladder.

Patients with peptic ulcer or pre-ulcerous dyspepsias may have symptoms mimicking gall bladder disease. In every large clinic not a few patients with undiagnosed duodenal ulcer have gall bladder operations. An obese sthenic woman with upper abdominal dyspepsia and pain suggestive of biliary colic presents herself. Physical examination reveals no differential information. The Graham-Cole test reveals a poorly functioning gall bladder. Unless the X-ray examination includes the upper intestinal tract, a duodenal ulcer may be overlooked and operation for cholecystitis advised. Miller (26), Pancoast (27) and others have pointed out that the irritable duodenum of ulcer or duodenitis frequently gives rise to a faint or absent gall bladder shadow due to lack of closure of the sphincter of Oddi. A second reason for failure to diagnose ulcer in these cases is that the presence of colic focuses attention away from ulcer and on the gall bladder.

Wilkie (28) has described attacks of acute pain suggestive of biliary colic in patients who on accurate investigation or operation prove to have a chronic duodenal ulcer. He terms this combination of symptoms "cholecysto-duodenal syndrome" and states that 10%

of female patients referred to him in hospital practice for cholecystectomy were in fact suffering from duodenal ulcer.

The high ulcer incidence in gall bladder disease brings up two practical points:

(a) Ordering a cholecystogram without an accompanying examination of the upper gastro-intestinal tract may bring one to diagnostic grief.

(b) In patients who have indigestion after cholecystectomy, whether ulcer is demonstrated by X-ray or not, it always pays to try diet-alkali management for ulcer. Not infrequently patients who have post-operative indigestion which cannot be relieved by gall bladder diet, cholagogues and antispasmodics, obtain relief from alkalis. The finding of duodenal ulcer in a patient who has had cholecystectomy does not signify that the cholecystectomy was unnecessary.

4. *Anxiety Neurosis*: Only two patients are listed in Table III as having poor results following cholecystectomy because of anxiety neurosis. In these two the neurosis dominated the clinical picture both before and after operation and in retrospect there was perhaps a poor indication for cholecystectomy. However, 25% of patients of the entire group (see Table IV)

TABLE IV

Associated diseases in 165 patients with biliary tract operations

Duodenal ulcer	12%
Ulcer syndrome (X-ray negative for ulcer)	4%
Spastic Colon	41%
Post-operative Hernia after Cholecystectomy	8%
Endocrine Disorders	
(a) Menopausal symptoms	16%
(b) Hypothyroidism and thyroid adenoma	5%
(c) Hypopituitarism	1%
(d) Obesity	8%
Diabetes mellitus	4%
Essential hypertension, coronary disease and their complications	22%
Arthritis	35%
Anxiety Neurosis	25%

had anxiety neurosis. The more unstable the patient the more likely will she give audience to trivial residual symptoms. In general the clinic patients and the Jewish patients predominated in this group. Deaver and Bortz (2) found that highly neurotic persons often exhibit a continuance of symptoms even after removal of a definitely diseased gall bladder, and many patients in their series complaining of persistence of symptoms were of this type.

5. *Gastro-intestinal Allergy* was shown to be the cause of residual symptoms in two cases. One patient of an allergic family, had an eczema for years, had dyspeptic symptoms before and after operation. Skin tests were positive to many foods, but some of the foods she was positive to on skin test could be tolerated in her intestinal tract. Elimination diet by trial and error methods and drug treatment gave complete subsidence of symptoms. Dietary indiscretions caused immediate return of symptoms.

6. *Diseases of distant organs* may cause symptoms

simulating biliary disease. In two of our patients there was epigastric indigestion thought to be biliary in origin. From each a stoneless gall bladder with a minor degree of pathology was removed. Post-operatively the indigestion was unchanged. Investigation disclosed one case to have pelvic tuberculosis, the other pyelonephritis.

7. *Endocrine disorders*, especially menopause, were found to be of great importance, probably because they make the patient more irritable in both the cerebral and visceral zones.

RESULTS OF CHOLECYSTOSTOMY

31 patients underwent 34 cholecystostomies, three of the patients having two cholecystostomies each. Only 5 of the 31 patients (16%) obtained relief of colic and indigestion. 14 later underwent cholecystectomy because of recurrence of colic. An additional 4 should have been re-operated for recurrent colic, but operation was refused or contraindicated. Thus in 18 patients (58%), there was severe recurrent colic. In 7 patients (23%) there was relief of colic but persistent recurrent indigestion.

Our figures in no way represent what may be expected from cholecystostomy, as our series includes a large number of patients who had cholecystectomy after failure of relief from cholecystostomy. Christopher (29) states that 50% of patients who had cholecystostomy had no subsequent biliary distress. 25% of his series had mild residual symptoms and 25% had severe symptoms. Half of this last group were later submitted to cholecystectomy.

Cattell (8) reported 71.7% of patients unimproved after cholecystostomy, in half of whom secondary operation was necessary.

EXPLORATORY OPERATIONS ON THE GALL BLADDER

In twelve patients with a pre-operative diagnosis of chronic cholecystitis, exploration revealed insufficient gross evidence of gall bladder disease to warrant removal. Duodenal ulcer was found at operation or diagnosed subsequent to operation in six of these patients. The course of an additional three patients substantiated a diagnosis of anxiety neurosis and spastic constipation. The course of the remaining three showed these patients to have cholecystitis.

In four of the 12 patients who were explored but no cholecystectomy done, there was recurrence of symptoms of sufficient degree that a secondary operation of cholecystectomy was performed. Two of these had colic previous to the secondary operation, two had persistent indigestion. The only one who had cure of symptoms was one in whom stones were found.

It is important to carefully survey the patient clinically and roentgenologically before operation. The criteria for operation consist clinically in the presence of colic and positive roentgen evidence. When both of these criteria are fulfilled and the surgeon encounters a normal looking gall bladder without stones and no other lesion is found, a difficult problem of operative judgment presents itself. Many surgeons feel that if there is a definite history of biliary colic and positive roentgen evidence of cholecystitis, cholecystectomy is warranted (Stanton (10), Lahey (30)).

IV

ASSOCIATED DISEASES

Table IV shows the incidence of those diseases most commonly associated with cholecystitis.

333 associated diagnoses were recorded in the 165 cases, or an average of 2.4 per patient. Adding the gall bladder disease each patient had 3.4 diagnoses. A previous study of clinic patients suffering from gastrointestinal disorders by Meyers and Sandweiss (31) showed an average of 4.4 diagnoses per patient.

The incidence of diabetes mellitus (4%) is low compared to the figures of Johnston (32) who reports an incidence of 7.2% of diabetes in 194 cases of gall bladder disease.

Menopausal symptoms were present in 16% of cases. The remainder of endocrine disorders were chiefly concerned with fat metabolism. Hypothyroidism was present in 5% of our series, hypopituitarism in 1% and obesity in 8%.

Degenerative cardiovascular diseases, as essential hypertension and its sequelae, and coronary sclerosis and thrombosis forms a definite group (22%). There is some relation here to the age of the patient but the figures show that degenerative vascular disease and cholecystitis are commonly associated.

Arthritis, present in 35% of the cases, was practically always hypertrophic in type. Rehfuess and Nelson (20) report an incidence of 44% of muscle or joint involvement in 125 patients who had had gall bladder surgery.

Anxiety neurosis was common (25%). No causal relation to the cholecystitis is considered here.

The incidence of post-operative hernia in the cholecystomized group was 8%, after all biliary tract operations 9.5%.

An interesting hypothesis to explain the co-incidence of the above associated diseases is as follows: The patient is obese, due purely to overeating or with an endocrine disorder, as hypothyroidism, hypopituitarism or menopause as a contributing factor. The body's ability to handle fat is impaired. Cholesterol is deposited in the gall bladder wall or lumen in excess amounts. This initiates stones and later infection. The vascular disease may result from obesity with increased strain on the heart, or deposit of products of abnormal fat metabolism in the vessel wall, or contraction of vessel wall due to endocrinopathy. The hypertrophic arthritis may be due to a metabolic disturbance or obesity.

LIFE TIME NATURE OF BILIARY TRACT DISEASE

When a patient presents herself with the usual symptoms and objective findings of gall bladder disease and a cholecystectomy is recommended, the patient expects (and so does the physician) that following removal of her gall bladder she will be symptomatically and actually well. The patient draws an analogy to appendicitis, once the offending gall bladder or stones are out she will be perfectly well. This expectation was realized in only half of our cases (54%). It is important if we are not to leave a false impression to think of the disease as affecting not only the gall bladder but the entire biliary tract. Removal of the gall bladder may remove the chief seat of inflammation, and removal of the gall stones may remove the source of much of the colic. Operation will not, however, remove the inflammation in the biliary

ducts, liver and pancreas, nor affect the metabolic disturbance which may have been the cause of stone formation. In fact, it may precipitate motor disturbances of the sphincter of Oddi or biliary tree.

One is impressed with the fact that the longer one follows cholecystectomized patients the higher is the incidence of biliary tract sequelae. A patient may do pretty well after a cholecystectomy, then two or ten years after operation colics may recur. Or a patient who has been eating everything finds that careful food selection is necessary to prevent indigestion. With the concept of the life time nature of the disease in mind, one should supervise a patient after cholecystectomy instead of allowing her to assume that she will have no further difficulties.

That gall bladder disease may be merely a link in a chain of related disturbances is suggested by the following:

1. The life time nature of biliary tract symptoms.
2. The frequent repetition of certain associated diseases as arthritis, cardiovascular disease, diabetes, etc.
3. The frequent association of metabolic and endocrine factors as hypothyroidism, hypopituitarism, obesity, pregnancy, menopause, hypercholesterolemia.
4. The appearance of gall bladder disease in a patient of a certain constitutional type, the majority being in those of sthenic habitus.
5. Despite definite biliary tract symptoms and findings pre-operatively, at operation the gross pathology may be found to be slight.

May not "gall bladder disease" be merely one phase of a more fundamental and more inclusive disturbance, the nature of which we now have only fragmentary knowledge? If this is true cholecystectomy may give relief only by breaking the chain at a certain phase, with the possibility of recurrence of similar or other type of symptoms.

TREATMENT

The selection of patients to be operated is of great importance. The most favorable patients for cholecystectomy are those having colic due to the presence of stones demonstrated pre-operatively, or patients with colic who have a non-functioning gall bladder. The most unfavorable cases are those in whom indigestion but no colic was present pre-operatively and regardless if stones were demonstrated pre-operatively.

Medical management commencing immediately after operation will yield more satisfactory results than leaving the patient to his own devices in the post-operative period. Usually some dietetic supervision and regulation of the bowels is all that is required. When recurrent symptoms appear after cholecystectomy a complete survey should be made of the patient to determine the nature of the biliary lesion as well as to detect the presence of such extra-biliary lesions as duodenal ulcer, spastic colon, anxiety state, etc. Study of the patient for the presence of such associated diseases as coronary disease, diabetes mellitus, arthritis, etc., is important.

B. B. Vincent Lyon has epitomized the treatment of biliary tract disease as diet, drugs and drainage. A bland diet is prescribed, low in fat if the patient is obese, higher in butter, cream and eggs if the patient has been undernourished.

Drug treatment includes cholagogics as bile salts or their derivatives. Anti-spasmodics as belladonna and

sedatives as phenobarbital or bromides are very useful. Determination of gastric acidity with the judicious use of alkalis or hydrochloric acid may give additional relief for the feeling of epigastric distention. Regulation of the bowels without the use of irritant cathartics is important.

In addition some medicine to combat attacks of pain may be necessary as a capsule of codeine and aspirin, a suppository of opium and belladonna or an occasional hypodermic of morphine. Recently Walters (17) has advocated the use of amyl nitrite and aminophyllin in colics after cholecystectomy, which he states are more efficient than morphine in opening the common duct sphincter with consequent fall of the intraductal pressure. The above pain-lulling remedies are particularly needed in convalescent colic and biliary dyskinetic attacks.

Duodenal drainage may be helpful. Removal of foci of infection and daily exercise should be prescribed.

The endocrine and metabolic feature of the individual case may require treatment.

Often the crucial point in relieving symptoms will be the administration of thyroid extract which decreases weight, adds to intestinal tone, relieves constipation and adds to the general feeling of well-being.

Many of these patients are of a neurotic make-up and in the presence of some indigestion forget about the pre-operative colic and its subsidence following operation. Treatment for migraine, menopausal symptoms, assurance that a secondary operation will be unnecessary and moral support are indicated.

SUMMARY

A series of 165 patients who had 199 operations for biliary tract disease were studied on the average 7½ years after operation.

I. *End results of cholecystectomy.*

In a series of 136 patients who underwent cholecystectomy, 83% of those with calculous cholecystitis benefited from the operation and only 41% of those with non-calculous cholecystitis benefited.

Where pre-operative colic was present and regardless if stones were found at operation, 76% benefited from cholecystectomy; with no pre-operative colic, only 41% were benefited.

II. *Causes of recurrent biliary symptoms in cholecystectomized patients.*

The causes for symptoms of marked degree include: residual biliary tract infection, biliary dyskinesia, common duct stones, chronic cholangitis and cystic duct stones.

III. *Extra-biliary causes for symptoms after cholecystectomy.*

(a) Mistakes in diagnosis. Long after cholecystectomy was performed the distress for which operation was performed was thought in retrospect to be due to one of the following conditions: peptic ulcer, neurosis, gastro-intestinal allergy, pelvic tuberculosis, pyelonephritis.

(b) Appearance of abdominal symptoms due to new pathology. Patients who have undergone cholecystectomy are not immune to the general run of gastro-intestinal diseases as duodenal ulcer, spastic colon and intestinal adhesions or to such general conditions as anxiety neurosis and endocrinopathy. These conditions may give biliary-like symptoms.

IV. *Associated Diseases.*

An average of 3.4 diseases was present in each of

our patients who underwent biliary tract surgery. The diseases most commonly associated with pathology in the biliary tract were found to be degenerative vascular disease as coronary disease and essential hypertension, endocrine disturbances as menopause, hypothyroidism, hypopituitarism and obesity, diabetes mellitus, chronic hypertrophic arthritis, anxiety neurosis and the gastro-intestinal diseases listed above.

V. The life time nature of biliary tract disease in some patients, the frequent repetition of the associated diseases listed above and the metabolic and endocrine

background so often present suggest that biliary tract disease may be only one phase of a more fundamental and more inclusive disturbance.

VI. Given a patient with a gall bladder scar and abdominal symptoms, careful analysis will show the symptoms to be due to

(a) Persistent or recurrent biliary tract disease.

(b) Extra-biliary disease, uncorrected by cholecystectomy because the original symptoms were due to pathology outside of the biliary tract.

(c) The appearance of new abdominal pathology subsequent to and independent of the cholecystectomy.

Mycotic Infections of the Stomach

By

CARL BEARSE, M.D., F.A.C.S.
BOSTON, MASSACHUSETTS

WHILE in recent years a great deal of interest has been shown in fungi and in diseases caused by them, particularly of the skin and lungs, the fact that they may be responsible for gastric lesions has been practically ignored. An opportunity to operate on a patient with an advanced mycotic infection of the stomach (4) convinced me not only that this condition should be considered in the differential diagnosis of gastric pathology but also that an early diagnosis was desirable.

There have been reports that fungi have caused gastritis (26), ulceration (1, 11, 15, 18, 28), and even perforation of the stomach (4, 5), but such reports have been comparatively few and infrequent. Since fungi may be pathogenic, it is possible that if more frequently sought, fungi might be found to be a more common cause of gastric infections than thus far considered.

Fungi have been found in 40 per cent of the oral pharyngeal cavities of apparently healthy people (7, 20, 29). Since fungi are very prevalent in food, water

and air, it is to be expected that due to the swallowing of food and saliva, fungi may be carried to the stomach and found in the gastric contents. Although there are no reports dealing with the relative incidence of fungi in the mouth and the stomach at the same time, there are reports of fungi being present in 40 to 60 per cent of stomach aspirations (9, 10, 22). Crasset reported that he found moulds in twenty out of thirty stomachs examined after death; Zalesky (31) and Maresch (18) also found fungi in gastric contents at autopsy. Fungi have been found in stools in a correspondingly high percentage (24). The fungus most frequently found in mycotic infections of the stomach was *Monilia albicans*; in some instances, *Aspergillus* was the offending organism; and rarely the ray fungus was isolated. A positive report that fungi are present in gastric contents should be made only if there are at least 10 colonies per plate on the first culture (24).

If there is any local circulatory disturbance of the gastric mucosa, or if its immunity is lessened (29), pathogenic fungi may invade it and form thick dip-

theria-like membranes. Should there be injury or further local vascular damage, this condition may go on to ulceration (2, 3, 10, 16, 23). A typical mycotic ulcer is usually found on the lesser curvature of the stomach. At times, instead of a single ulcer, there may be multiple lesions; these ulcerations may vary in size from minute lesions to ulcerations so large that they may involve the whole stomach. Gradually such an ulceration may penetrate to the muscularis (5) or even to the serous membrane (17). In one instance (5), perforation with peritonitis resulted, and in another case (4), fistulous formation occurred after a perforation.

Pathological examination of the necrotic tissues and adjacent layers of a mycotic ulceration reveals that they are infested with moulds—branching filaments with small, bulb-like tips, lacking reproductive forms. There is very little leukocytic reaction. The base of the ulcer is made up of necrotic tissue, and there is thrombosis in the underlying vessels; the periphery of the ulcer is dark and granular and shows a hemorrhagic inflammatory reaction. In an actinomycotic ulcer of the stomach, typical sulphur bodies of the *actinomyces bovis* (ray fungi) may be found, but they are usually present only in a very limited area of the lesion (6, 14, 25, 30).

The symptoms are strikingly like those of a functional gastric disturbance or of a peptic ulcer (21); namely, pain or epigastric distress, heartburn, belching, a sense of fullness, nausea, and vomiting. There is nothing definite in the symptomatology to differentiate mycotic infections from other gastric lesions.

As far as we know, a mycotic gastric lesion has not been recognized before operation. Diagnosis has thus far been made only at operation or at biopsy.

A gastric mycotic infection should be thought of whenever the vomitus, blood-streaked or otherwise, contains strands of pathogenic moulds. Should these fungi also be found in the gastric contents that have been obtained by a stomach tube; uncontaminated by moulds that may be present in the mouth or pharynx, then a mycotic lesion should be suspected. The suspicion is further strengthened if these fungi can be cultured on acid fungus media, and the diagnosis is warranted if inoculation (29) of this culture into a rabbit results in endothelial proliferation and giant cell formation together with an abundant growth of fungi without much of any inflammatory reaction. For further confirmation of the diagnosis, positive blood agglutination and intradermal tests for *Monilia* have been used (13). Blood cultures have also been found to be positive for *Monilia* by Irish (12) in 40 per cent of his cases. In actinomycotic lesions where there is a sinus or sinuses, a diagnosis may be made from the sinus curettings which may disclose the ray fungi (19). If a patient with an unsuspected gastric mycotic lesion is operated upon, the diagnosis should be suggested if upon incising the parietal peritoneum, necrotic tissue without any frank purulent manifestations is found. It should also be thought of if a membrane is found in the stomach that can be easily removed but leaves behind a bleeding surface, or if an ulcer is disclosed that has a necrotic base and brownish irregular periphery. Should a biopsy of the suspicious tissue disclose abundant fungi, then the confirmatory tests already mentioned should be carried out.

Buchanan (8), on the other hand, doubts the value of yeast cultures in general. He advises that study be

made not only of the presence of the organisms but also of their numerous biological products—both endogenous and exogenous. However, it does seem that the finding of pathogenic moulds in vomitus that can be cultured in appropriate media, inoculation of this culture into a rabbit with a resulting characteristic mycotic reaction, positive blood cultures, positive blood agglutinations and intradermal tests, warrant a diagnosis of a mycotic infection, particularly when there is a lack of evidence of any other lesions.

We feel that the more frequent use of gastroscopy together with increasing skill in recognizing the membrane of a typical mycotic gastritis or ulceration should help to make an early diagnosis possible.

There have not been enough case reports on the subject of gastric mycosis to warrant a reliable prognosis. The few cases that did come to operation developed no complications that could be attributed to the fungi themselves. In the rare actinomycotic infection especially, the prognosis should be guarded due to the possibility that metastasis to the liver may already have taken place.

If a diagnosis of a gastric mycotic infection could be made when there is only a gastritis or an early ulceration, the treatment consists in the administration of iodides to the point of tolerance. Sodium iodide (15 grains) injected intravenously or given by mouth in a syrup of hydriodic acid has been recommended in *Monilia* infections of the respiratory tract (12) and might be equally effective in gastric mycotic lesions. Neocarsphenamine and vaccines (13)—either auto-genous (27) or a stock vaccine including many strains, as well as non-specific vaccine (typhoid-paratyphoid) (27)—have also been used. Dietary regulation has not been of any help.

In abdominal actinomycosis, X-ray treatment has been reported as being of value (19). While this was supplemented by ultraviolet irradiation, sunbaths, iodides internally, and the application of iodine to the walls of the sinus tracts, it was felt that X-ray contributed most to the recovery of patients with this condition. A combination of both X-ray and iodides should be effective.

When the ulceration becomes so extensive that perforation takes place or repeated hemorrhages result, then there is no alternative except operation.

CONCLUSIONS

1. Fungi may cause a gastritis, ulceration and even go on to perforation.

2. There are no characteristic symptoms. The complaints are similar to those in functional disturbances of the stomach or in peptic ulcer.

3. The diagnosis should be thought of when pathogenic fungi are found in the vomitus. The suspicion should be strengthened when these fungi are found in uncontaminated gastric contents and can also be cultured in appropriate media. Should the inoculation of this culture into a rabbit give a typical reaction and be corroborated by positive blood cultures, intradermal tests and blood agglutinations, a diagnosis of a mycotic infection is warranted.

4. The more frequent use of the gastroscope together with increasing skill in recognizing typical mycotic gastritis or ulceration should help to make an early diagnosis possible.

5. No reliable prognosis can be given owing to a lack of cases on which to base a definite opinion. There

were no complications that could be attributed to the fungi themselves in those cases where operation was performed. If the lesion is due to the ray fungus, the prognosis must be definitely guarded due to the possibility that metastasis to the liver may already be present.

6. In uncomplicated cases, iodides to the point of tolerance should be administered. If there are actinomycotic sinuses; then X-ray treatment should also be used.

7. For complications such as perforation or repeated hemorrhages, operation is necessary.

Studies in Calcium Metabolism: II. Further Contributions to the Comparative Studies of the Physico-Chemical Properties of the Gluconate and Cevitamate of Calcium and of Vitamin C

By

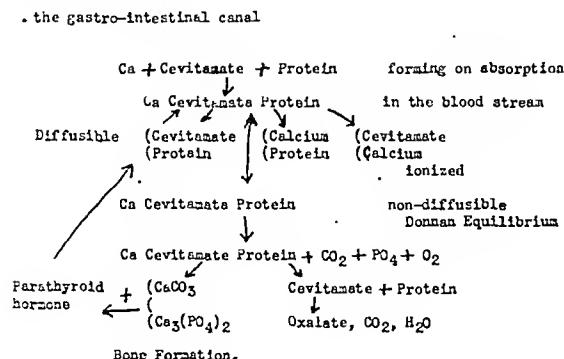

SIMON L. RUSKIN, M.D.

NEW YORK, NEW YORK
and

RAYMOND JONNARD

PARIS, FRANCE

AS a presumptive schema of calcium metabolism involving cevitic acid, the following formulas are presented:

Following the comparison of Calcium Cevitamate and calcium gluconate as to its physical properties such as solubility, ionization and depression of the

freezing point, it becomes important to observe how these substances behave in the presence of blood serum.

For this investigation the usual chemical procedures could give us no possibilities of analysis since we could not tell how much of the preparation combined with the blood proteins. This factor is important in view of the observations of the Vienna School (Pick (9), Spiro (7), Kylin (8)) that the absorption of a foreign substance introduced into the blood stream was directly proportional to its combining powers with the blood proteins. And for a substance to be utilizable by the tissues it must be bound to the blood proteins, the same being true for nutritional substances. Conversely, substances not combining with blood proteins are toxic and Jonnard has suggested this as a factor in allergy.

Fortunately, such investigation has become practical by physical analysis through the notable improvement of the interferential refractometer made by R. Jonnard (3), (in the Laboratory of Animal Biology of the University of Paris), making possible the readings

two decimal points farther than the Abbe refractometer. This improvement in technique has enlarged the scope of possibilities to include many biologic reactions described in a series of papers by Jonnard, and by Jonnard, Faillie and Zuckerkandl. In their last report from the Laboratoire de physiologic du Travail du Conservatoire des Arts et Metiers et Laboratoire d'hematologie de l' Hopital St. Louis (service due Dr. Tzanck), they describe in detail the technique and results of study of chemical reactions in the blood serum by changes in the refractive index. This has led to striking additions to our knowledge of the reactions of cholesterol, bile salts, di-iodo-tyrosine, NaCl and KCl.

The presence of Dr. Jonnard in this country on a fellowship from the University of Paris afforded the unusual opportunity of applying these methods to the study of the Calcium Salts by the principles of the Interferometric Method.

In effect, it may be stated that the index of the refraction faithfully follows the disturbances undergone by the molecular structure of the bodies under the influence of physical or chemical reactions. This makes possible rapid serial studies of biologic liquids of complex structure. The same method has likewise adduced arguments in favor of the physico-chemical constance of the protein molecules of the serum (35) a conception too little recognized. In a mixture of reagents added to the blood serum several minima may appear showing that several differently reacting substances have been added. In this manner it has been possible to study groups of bacterial antigens in one solution. The minimum of the refractive index thus shows the point of complete chemical reaction between the reagent and the blood serum.

A series of experiments were conducted; first the fixation of Vitamin C in the blood serum was studied, then the fixation of Calcium Cevitamate. A comparative study of the fixation of Calcium Cevitamate and calcium gluconate revealed an interesting difference in reaction to serum proteins. This led us to investigate the mechanism of the action of calcium and of Vitamin C in the serum. Since no study of serum calcium would be complete without investigation of the influence of the parathyroid hormone, an extended series of experiments were conducted. Some of the data tends to support the schema of serum calcium proposed in this paper and further study is planned.

FIXATION OF VITAMIN C IN THE SERUM

The interferometric method has already demonstrated that numerous substances added to the blood stream find themselves fixed in it chemically in variable amounts according to their nature, their part in the general metabolism and the pathological condition (5, 6, 7) of the blood donor. The limit of fixation or saturation point corresponds exactly with that determined by more complicated chemical or physical methods (8) in some experiments made on this subject.

If one adds progressively increasing amounts of cevitamic acid (in fresh solution in boiled distilled water) to a constant volume of serum (which in our experiments was a dilution of 83.3%), one can state that a minimum of the index of refraction occurs for a concentration of 0.5 mg. Vitamin C per cc. of serum. This was verified on seven different human sera.

These sera were from hospitalized patients not suffering from scurvy and a residual Vitamin C content must be added to our findings.

As in the case of the substances previously studied by one of us (Dr. Jonnard), there is a certain constancy between the figures found for different concentrations of serum, as is seen in the following example in which the minimum appears for 0.1 mg. per cc. of serum diluted to 16.75% or a one-fifth concentration.

C° VC	Refractive Index
0.0	1.335680
0.05 mg. per cc.	1.335615
0.1	1.335622
0.2	1.335738
0.3	1.335738
0.4	1.335756
0.5	1.335869

From what is known through previous work done with this method, it therefore seems that the serum is capable of fixing 0.5 mg. Vitamin C per cc. combined chemically with the proteins.

FIXATION OF CALCIUM CEVITAMATE

In view of these results it is interesting to see how the presence of Calcium can condition the activity of the Vitamin C on the index of the serum when Calcium Cevitamate is employed.

A first experiment made on a very small sample of serum placed the minimum index between 0.6 mg. and 1.0 mg. of product per cc. of serum.

Cone. Cal. Cevitamate	Index
0.2	1.344998
0.5	1.345321
1.0 mg. per cc.	1.345223

The same experiment repeated under the same conditions on larger samples gave results arranged in the following table:

Conc. Cal. Cevitamate	Index
0.00	1.344050
0.5	1.344812
0.6	1.344910
0.8	1.344842
1.0	1.344992
1.5	1.345223
2.0	1.345329

A very sharp minimum, therefore, appears for a concentration of 0.8 mg. of Calcium Cevitamate per cc. of serum. This is much greater than that resulting from the presence of Vitamin C. If one takes into consideration the respective molecular weights of these substances calculated from the formula one finds the calcium represents only about 9.34% of the total molecular weight. The fall of the index of the serum in the presence of this product at the amount of 0.8 mg. per cc. cannot, therefore, be attributed to the presence of calcium ions alone, particularly since the latter added alone in the form of Ca Cl_2 produces a minimum of the refraction of the serum at the amount of 0.4 to 0.5 mg. per cc. From these measurements one may say that Calcium Cevitamate possesses specific physico-chemical properties conferred by the simultaneous presence of the reacting calcium and the Vitamin C. It may be added that the phenomenon cannot be attributed either to the eventual dissociation of the

product under the influence of the dilution, for diluted in pure water its index follows a straight line:

Conc. Cal. Cevitamate (C° ccvitamate)	Index
0.2	1.333034
0.5	1.333119
1.0 mgm. per cc.	1.333218

COMPARATIVE FIXATION OF CALCIUM GLUCONATE

Referring back to the subject of this paper, it is especially striking to observe that the fixation of the calcium gluconate by the serum proteins is remarkably weaker than in the case of Calcium Cevitamate. Indeed, in the case of calcium gluconate a minimum of refraction appears for an amount of product of 0.2 mg. per cc. of serum. The trend of the phenomenon is represented in the following table summing up one of our experiments:

Conc. Final Calcium Gluconate	Refractive Index
0.0	1.343731
0.1	1.343710
0.2	1.343698
0.3	1.343735
0.5	1.343886

It is observed that up to a concentration of the product attaining .2 mgs. per cc. of serum the index varies in a noticeably regular manner. It is, therefore, possible to conclude that probably the saturation of the proteins is attained with about 0.2 mgs. of Calcium gluconate per cc. of serum. This relatively small amount checks also with the weak ionization of the calcium gluconate in our chart on the relative ionization in the first pages of this article as well as with our clinical experiences regarding the relative merit of Calcium Cevitamate as compared to calcium gluconate. The data on Calcium Cevitamate thus tends to support the conceptions of the Vienna School (Pick, Zuckerkandl, Hendl) according to which the biological activity of the products would be conditioned by their preliminary combination with the blood or tissue proteins. In our tests with Calcium Cevitamate the availability of the product is greater and more efficient since it can combine in greater quantity with the serum proteins, the intimate nature and mechanism of this combination remaining for further elucidation.

MECHANISM OF THE ACTION OF CALCIUM AND OF VITAMIN C IN THE SERUM

The question arises how these two products will reciprocally modify their behavior when they are added to it simultaneously. This point seems important to determine in order to see what part the Vitamin C may play in the metabolism of the calcium. With this in mind, we have compared in a certain number of samples of human serum at a constant concentration (83.3% for the convenience of the measurements of volume of the reagents) the index of refraction in:

- pure serum in absence of any reagent.
- serum plus 0.5 mg. of Ca CL_2 per cc.
- serum plus 0.5 mg. of Cevitamic acid per cc.
- serum plus Ca CL_2 and Cevitamic acid same final concentration.

The results are contained in the following table:

Specimen Number	Serum	Serum with Cevitamic Acid	Serum with Ca CL_2	Serum with Both Reagents
BH 12699	1.342568	1.342460	1.342453	1.342777
BH 12910	1.343484	1.343478	1.343355	1.343637
BH 12762	1.	1.343508	1.343141	1.343727
BH 12751	1.342897	1.342615	1.342726	1.343106

One sees that the two products added alone lower the index of the serum as has been previously shown, while they raise it strongly when they are added simultaneously in the same proportions. This does not occur when the same experiment is repeated by replacing the serum by the same quantity of distilled water, as is seen in the following figures:

1. Index of water used 1.333030
2. Water plus 0.5 mg. Cevitamic Acid per cc. 1.333034
3. Water plus 0.5 mg. Ca CL_2 per cc. 1.333050
4. Water plus Ca CL_2 and Cevitamic Acid same conc. 1.333058

The difference here is too weak to be attributed to a combination between the two products added by comparison with the results obtained in presence of serum. We must, therefore, admit that a combination in which the calcium and Vitamin C ions react most strongly requires, in the conditions of these experiments, the presence of blood serum and a concentration exactly that which for the two products taken separately produce the minimum of refraction, (the saturation point) of the fluid. One can also point out that the molecularly reacted Calcium Cevitamate presents a better approach to the saturation point of the serum than the addition of calcium and Vitamin C separately in unbalanced proportion. It will also be later demonstrated that the concentration of the combining elements have a definite optimum point of reaction.

One may, perhaps, assume that the reaction which in these measurements shows the important increase of index observed takes place between the new protein molecules formed on the one hand with the calcium and on the other hand with the Vitamin C, that is, calcium protein and Vitamin C protein. Although the study of the factors involved is particularly difficult, we propose to return to it further on. Nevertheless, at present let us say that to the support of this conception comes the following observation: if in the experiment, conducted in the preceding manner, the quantities of the substances added are noticeably less so that the saturation of the proteins respectively by Vitamin C and Ca CL_2 is not attained, the increase of index produced by their simultaneous presence in the serum no longer takes place, as is seen in the following example:

Serum BH 12692	C° final 83.3%.
Index of pure serum	1.342885
Serum plus 0.25 mg. Cevitamic Acid per cc.	1.342808
Serum plus 0.25 mg. Ca CL_2 per cc.	1.342812
Serum plus Ca CL_2 and Cevitamic Acid same conc.	1.342744

In this case the proteins are not saturated and the reaction is strongly concealed by the presence of non-transformed proteins capable of reacting in numerous

different ways. This explanation is comparable to that suggested by one of us (Dr. Jonnard) with F. Zuckerkandl, for the interpretation of the characteristics of the variations of the refractive index occurring in the mixture of two portions of serum, one of which was heated to 56° C. and the other kept at room temperature. In these same researches it has likewise been proven that the specific disturbance of refraction in the case of the existence of a true "zone phenomenon" evidence of a chemical reaction, were likewise concealed when the quantities of inducing products added were greater than those inducing the minimum of the index of the serum. Likewise in the case of the reaction with which we are concerned it is no longer possible to demonstrate a characteristic variation of the refractive index for any proportion of the product added if one of them is in too great quantity, as is the case of the following example:

Serum AML at 83.3% plus 1 mg. Cevitamic Acid.

C° final CaCl ₂	Index of Refraction
0.0	1.344408
0.1 mgm. per cc.	1.345119
0.2	1.344779
0.3	1.345018
0.4	1.344801
0.5	1.344931
0.6	1.345009
0.8	1.345188
1.0	1.344967

The variation of index is this time entirely irregular and shows nothing characteristic.

A composite of the findings shows the following:

We have sought to observe whether its presence can modify the reaction which appears when Vitamin C and Ca CL₂ are added simultaneously in the blood serum. With this in mind we have compared the variations of index of the serum:

(a) In the simultaneous presence of the two products mentioned.

(b) In the same case in the supplementary presence of 5 units of parathormone (Lilly).

(c) In the presence of the same quantity of hormone alone. The following are the results:

Serum BH 12751 Final conc. 60%.

1. Index of pure serum	1.342897
2. Serum plus Ca CL ₂ and Cevitamic Acid	1.343106
3. Serum plus Ca CL ₂ and Cevitamic Acid, plus hormone	1.343167
4. Serum plus hormone alone	1.343017

No characteristic phenomenon is revealed in this experiment, the same is true if one varies the quantity of hormone in presence of the same proportions of Vitamin C and of Ca CL₂, that is, respectively 0.5 mg. per cc. of each as is seen below:

1. Index of the mixture in presence of 5 units of hormone	1.339713
2. Index of the mixture in presence of 10 units of hormone	1.340018
3. Index of the mixture in presence of 15 units of hormone	1.340300
4. Index of the mixture without hormone	1.339642

In the present case the product used added in pro-

Substance	% Solution by Weight	Conc. Moles. Liter	% Ionization	Yield Ca ions per cc. Sol.	Solubility	Saturation in Serum per cc.
Calcium Cevitamate	5%	0.123	74.6	.0037	100%	
Calcium Cevitamato	10%	0.261	60.0	.0053		0.8 mg.
Calcium Cevitamate	20%	0.589	58.1	.0137		
Calcium Cevitamate	30%	1.008	55.3	.0226		
Neo-Calglucon	10%	0.125	47.8	.0048		0.2 mg.
Neo-Calglucon	20%	0.273	40.3	.0058	20%	
Calgluconate Powder	3%	0.072	48.6	.0014	3%	
Vitamin C					100%	0.5 mg.

It will thus be seen that the physico-chemical reactions check accurately with the changes in the refractive index supporting the utility of acute refractometry in the study of biologic fluids.

INFLUENCE OF THE PARATHYROID HORMONE

Regarding the possible influence of the parathyroid hormone on these reactions, advanced by one of us (Dr. Ruskin) from what is known of its part in ossification, it was interesting to study it by the same method.

gressive quantities to the serum does not seem to induce characteristic changes of the index.

Parathormone Units	Index of serum at 60% BH 12751	Index Serum BH 12737
0	1.342897	1.339642
5	1.343017	1.339642
10	1.343576	1.339642
15	1.343919	1.339642
20	1.343919	1.340441
25	1.343919	1.340700
30	1.343919	1.340864

In spite of the apparent negative results we wish to publish this experiment as suggestive of the point that the hormone does not react with the blood serum but enters into chemical relationship with the bone tissue.

SUMMARY

1. A comparative study of the solubility and ionization of Calcium Cevitamate and calcium gluconate shows the markedly greater solubility and ionization of the Calcium Cevitamate.

2. The yield of calcium ion per cc. of solution is 20 to 60 times greater for Calcium Cevitamate than for calcium gluconate.

3. The combining power of Calcium Cevitamate with serum proteins is four times greater than that of calcium gluconate, thus establishing a greater ration of utilization by the tissues for Calcium Cevitamate than for calcium gluconate.

4. A schema for serum calcium reactions is presented.

5. The saturation point of Vitamin C in human serum is established at somewhat above 0.5 mg. per cc.

6. Data is adduced towards the physico-chemical relationship of parathyroid hormone to the blood serum.

Untoward Effects Resulting From the Use of Large Doses of Vitamin B₁*

By

CHAS. LEROY STEINBERG, M.D.
ROCHESTER, NEW YORK

VARIOUS uses of Vitamin B₁ have been reported since its original discovery. These have been concerned chiefly with neurological disorders. Vorhaus (1) reported its successful therapeutics in peripheral neuritis. He gave 10 mgm. daily. Lasch and Bergel (2) have reported successful management of funicular myelosis associated with pernicious anemia with the use of Vitamin B₁. Jolliffe and Jaffe (3) have reported extensive studies on the value of Vitamin B₁ in the polyneuritis caused by alcoholic addiction. Others (4) have used Vitamin B₁ in neuritis associated with pregnancy.

With the increase in availability of Vitamin B₁ since its successful synthesis in July, 1936, by R. R. Williams, more extensive clinical use is sure to follow. To date no toxic symptoms have been reported from its use. Cowgill (5) has recently stated that no toxic symptoms of any kind were observed in doses approximating 25,000 or more times the estimated daily requirement. Its chemical formula has been determined as an amine. This amine is capable of being split into a pyrimidine base, C₄ H₅ N₃ SO₂, and a sulphur compound or thiazole, C₂ H₅ NOS, by means of sodium sulphite.

The writer has been interested in the clinical investigation of B₁ in the treatment of chronic arthritis. During the past two years various preparations of Vitamin B Complex and Vitamin B₁ have been employed in the treatment of over three hundred cases of this group of diseases. During this period several definite untoward symptoms have occurred with the use of large doses of Vitamin B₁, viz: herpes zoster

has occurred in three cases. In one of these three cases, the writer was able to produce herpes on two separate occasions. This was not possible in the other

two cases because the patients refused further treatment on account of the pain produced by herpes. Symptoms suggestive of smooth muscle spasm have occurred in other cases.

PROTOCOLS

Case 1. A white female, aged 51, was first seen January 16, 1937, at which time she gave a history of typical atrophic arthritis extending over a period of twenty-six years and involving most major joints of the body. After an initial period of seven months treatment with hemolytic streptococcus vaccine, massive doses of Vitamin B₁ were given both orally and by the parenteral route, that is, 800 units of Vitamin B₁ were given orally and 2,000 units were given intravenously at weekly intervals. At the end of four weeks of such treatment, the patient complained of severe burning pain along the outer border of the right arm and the midaxillary area of the right chest. Examination revealed typical lesions of herpes zoster in these regions. The Vitamin B₁ was stopped, and the herpes

*Department of Medicine, Rochester General Hospital.

disappeared in five weeks. Six weeks later the same dosage of Vitamin B₁ was given with similar return of the herpes zoster at the end of four weeks of such treatment. Cessation of the treatment resulted in disappearance of the herpetiform lesions in four weeks.

Case 2. A white male, aged 64, was first seen October 1, 1936, with typical hypertrophic arthritis of both hips and a lumbar spine. He was given 2,000 international units of Vitamin B₁ intravenously at weekly intervals, and this was supplemented by 800 international units of Vitamin B₁ daily by the oral route. At the end of five weeks of such treatment he developed typical herpes zoster involving the right side of the chest and the external surface of the right arm. Cessation of this treatment resulted in complete disappearance of the herpetiform lesions in three weeks.

Case 3. A white male, aged 58, was first seen November 22, 1935, with infectious arthritis involving both knee joints, duration eight months. During the Fall of 1936 he was given 1200 international units of Vitamin B₁ daily by the oral route. At the end of two months of such treatment he developed typical herpes zoster involving the right upper abdomen. Cessation of such treatment resulted in disappearance of the lesions at the end of two months.

Two other untoward symptoms have been noted in my clinical experience. In one patient nausea developed a few minutes after administration of 2,000 international units of Vitamin B₁ intravenously. This patient had been receiving 800 units of Vitamin B₁ orally for a period of six months. During the latter two months of this treatment, he had also received 2,000 units intravenously twice weekly. No untoward results were noted until the eighth week of the parenteral treatment. In addition this patient noted a sense of fullness in the epigastrium and a sense of con-

striction of the throat within two minutes after receiving the Vitamin B₁ intravenously. Another patient has noticed a sense of constriction in the throat and severe cramps when given 2,000 units of Vitamin B₁ intravenously. The latter patient developed this untoward effect after several months medication with the pure Vitamin B₁. Both these cases suggest either a sensitivity developing towards Vitamin B₁, or else that supersaturation of the tissues of the body with Vitamin B₁ may cause the untoward symptoms noted.

The above case histories would seem to indicate that large doses of Vitamin B₁ are capable of irritating the peripheral nerve plates. Apparently, this toxic symptom occurs in only a very small percentage of cases treated with massive doses of Vitamin B₁. In my own series it is less than one per cent (1%). However, one should be on guard in the use of this substance, and when an individual so treated begins to complain of intense burning pain in an unsuspected area, the administration of this vitamin should be stopped.

Melanosis Proctocoli

Preliminary Report of Twelve Cases*†

By

HARRY E. BACON, M.D., F.A.C.S.

PHILADELPHIA, PENNSYLVANIA

and

WILLIAM A. H. SCHEFFLER, M.D.

CAMDEN, NEW JERSEY

MELANOSIS proctocoli may be defined as a morbid condition of the large bowel characterized by the deposition of black or brown pigment in the mucous membrane, usually without any inflammatory process.

First referred to by Cruveilhier in 1829 (1), this disturbance of the bowel is worthy of consideration in that it is encountered occasionally during routine sigmoidoscopic examination, at operation and at necropsy. Virchow offered a brief description in 1847 (2) and called it "melanosis coli," while Solger (3) applied the term "colitis pigmentosa." By means of the sigmoidoscope, Pick in 1911 (4) recognized this medical curiosity as a distinct entity, and in his writings referred to it as the "brown bowel."

Melanosis proctocoli occurs in approximately .25 per

cent of patients examined sigmoidoscopically. It is more common in the male sex and between the ages of 30 and 50.

Various divergent and confusing hypotheses have been promulgated so far as the cause of colonic melanosis is concerned, and because the evidence is not conclusive it seems expedient to mention briefly some of the more important ones. The most significant and influential factors in the etiology are chronic intestinal stasis and the use of anthracene cathartics over a long period of time. That the latter plays an important role was first mentioned by Bartle (7). It is now generally conceded that chronic constipation is a contributing but not an initial etiologic factor, and that the pigmentation accompanies but does not cause the intestinal stasis. Bockus (8) contends that the deposition of pigment probably results from the phagocytosis of the pigment of the anthracene group. Chief among this group of cathartics is cascara, although

*Read before the "Proctologic Society," Graduate Hospital, University of Pennsylvania, December, 1937.
†From the Departments of Proctology, Temple University Hospital and Graduate Hospital of University of Pennsylvania.

senna, aloes, rhubarb and frangula have been mentioned as offenders. Virchow described the pigmentation as a hemochromatosis. Pick was of the opinion that it was due to the products of protein disintegration, which were acted on by tyrosinase ferment and converted into melanin. Hueck (9) brought forth the theory that the pigment does not belong to the melanin group but is a lipofuchsin; further, that the splitting of certain products of digestion gives rise to a "propigment" of a lipid nature, and this is affected by ferments, giving rise to the pigment. Synnott (10) attributed the condition to the metabolic pigment melanin, which is an autochthonous substance originating in loco by transformation of preexisting material. Obendorfer (11) explains the pigmentation on the basis that disturbances in protein metabolism may result in excess production of waste products. At an early date the ingestion of heavy metals, especially mercury and lead, was thought to be the cause (12, 13). Lignac (14) believed the condition to be due to hemorrhage with subsequent bacterial activity, while McFarland (15) adhered to the theory that the pigment was formed by an enzyme which acts on the intracellular substance of the stroma of the intestinal mucosa.

Lynch (16) considers it to be due to a disturbance in the chromogenic function of the liver.

So far as the pharmacognosy is concerned many of the vegetable laxatives contain principles closely allied to methylanthraquinone or glucosides which yield such substances on hydrolysis. Cascara belongs to this group whose activity depends upon the presence of one or more oxides of methylanthraquinone. The active principle of cascara as well as aloes, and frangula appears to be emodin, $C_{15}H_{10}O_2$ or trioxymethylanthraquinone.

Any portion of the colon from the ileocecal valve to the anorectal line may be the seat of the pigmentation. As would be expected, the greater number of cases are observed in the rectum and sigmoid by gastro-enterologists and proctologists. Bockus (17) found the pigmentation most intense in the rectum, diminishing from below upward. The color of the mucous membrane is somewhat variable, not only in different patients but in the same patient. It may be evenly distributed over a large area of the rectum or arranged in a patchy manner throughout. In a series of twelve cases, seen by the authors, only one was more or less uniformly involved. A deep reddish-brown or mahogany color is usual, although an inkish-black is not altogether uncommon. These pigmented areas are broken up into minute islands, polyhedral in shape, by fine yellow or light brown striae extending in an irregular fashion. The appearance is often likened to a toad's back (18), crocodile or snake skin (2), or a chow dog's tongue (7). It is quite apparent that the existence of inflammatory changes is entirely independent of the melanosis (8). Pick, in his report (4), is quite emphatic in this respect and remarks, "in the cases studied there were no secondary inflammatory changes, no ulcerations, scars or catarrhal states of proliferation." It has been mentioned that melanosis is much higher in carcinoma of the colon (19), although the writers have found but one such case in the literature, that of Bland-Sutton (20, 21).

The granules of pigment, which vary from 7 to 20 microns, are found within large mononuclear cells in the tunica propria. According to Zobel and Susnow

Photograph of a longitudinal section of rectal mucosa, showing dark brown and black areas of pigmentation in the tunica propria between the glands. A few areas of smaller size may be seen in the submucosa.

(22) the pigment is in the mucosal villi in mild cases, and in the advanced, in the region of the muscularis or scattered through it. Infrequently they may be seen in the submucosa (10) and in the mesocolic lymph nodes (23). As has been shown, the pigment contains no iron, shows no bile pigment, is never crystalline and is insoluble in acid and alkalis (24). In a splendid scientific dissertation on the Dopa reaction, Laidlaw (25) mentions that the test is specific for two kinds of cells, the melanoblast, a term including all melanin producing cells as distinguished from mere phagocytes, and a myelogenous leukocyte which has no connection with melanin production. Both have a ferment, an oxidase, which converts dopa into melanin. Blackening of the cell is called the dopa reaction. Study of a rectum and colon with diffuse melanosis, which was removed surgically, showed that the pigment cells were dopa negative; therefore, he concluded that there are no melanoblasts and no melanin in the colon, or in the rectum above the anorectal line. Boyd reasons as follows, "the pigmented cells are dopa-negative and are, therefore, melanophores that have taken up the pigment which has either been ingested in the food or synthesized in the bowel.

So far as the pigmentation of the mucosa is concerned, no symptoms are cited. Invariably the patient will mention a habitual constipation and the use of various laxatives, but upon questioning, after visualization of the melanosis through the proctoscope, he

will usually admit the prolonged use of cascara or one of the other cathartics.

Of the twelve cases observed, eight had taken cascara frequently and other laxatives, only one was quite emphatic that none of the group had been used. The ages of the patients ranged between 30 and 66. One was a colored male; all the others were white. There were six males and six females. In one case, a man of 66 years of age, the condition was associated with diverticulosis of the sigmoid.

There is little to be said so far as the treatment is concerned, except the withdrawal of anthracene cathartics and correction of the constipation usually will

be rewarded by disappearance of the pigmentation. It has been estimated that three to six months is required. This is approximately the period observed in our cases.

SUMMARY

Twelve cases of Melanosis Proctocoli have been reported. While the condition is relatively uncommon, it is by no means as infrequent as usually considered. The fact that it only can be visualized by sigmoidoscopy, again emphasizes the importance of a complete examination of the rectum and sigmoid in all cases coming under observation.

Carcinoma of Head of Pancreas Without Jaundice

By

CHARLES HAINES, M.D.
NEW YORK, NEW YORK

THE most common symptom of an advanced carcinoma of the head of the pancreas is a deepening jaundice. The carcinoma encroaches upon the common bile duct at its entrance into the duodenum damming back the bile into the biliary system and causing jaundice. It is safe to say that a diagnosis of carcinoma of the head of the pancreas would not be made unless the patient were jaundiced.

Thus it seems that the following case report of a carcinoma of the head of the pancreas without jaundice may be of interest.

CASE REPORT

M. W., 50 years of age, white, male, was first seen by me October 12, 1934. According to the patient's history he had been in good health until nine months previously. At that time he first noticed some discomfort in the upper abdomen which tended to come on after meals and which was not relieved by food. During these nine months the patient had had several attacks of nausea and vomiting. In spite of advice from his physician he had refused any satisfactory study of the gastro-intestinal tract.

About ten days before I first saw the patient, nausea and vomiting had become severe. The discomfort in the epigastrium became a constant pain. He was obliged to remain in bed. He could eat no solid foods and took only milk and cream.

At the time of my examination he was in acute distress.

During the half hour which I spent with him he vomited more than two quarts of dark green fluid.

Temperature was normal; pulse, 100 per minute. The tongue was dry and coated. The abdomen was markedly distended, especially across the epigastrium. There was no tenderness. No mass could be felt in the abdomen. No intestinal sounds were heard. Rectal examination showed no abnormality.

And there was no jaundice.

I made a diagnosis of pyloric obstruction.

The patient's stomach was drained by means of a Wangenstein tube. He was given large doses of 5% glucose intravenously and under the skin. He gradually improved.

A gastro-intestinal X-ray series was made. Films of the stomach and duodenum showed (1) a very large stomach; (2) a somewhat irregular pyloric ring; (3) considerable increase over the normal emptying time of the stomach; (4) a large six hour residue.

When the patient's general condition had improved as much as possible under the treatment outlined above, I operated. At operation I found the glands along the greater and lesser curvatures of the stomach and along the vertebral column markedly enlarged and stony hard; they were obviously involved in a neoplastic process. The head of the pancreas was also enlarged and stony hard. It was impossible to ascertain definitely where the neoplastic process had originated. The growth was pressing upon the duodenum in such a way as to cause a partial obstruction. I did a posterior gastro-enterostomy and re-

moved a lymph node which microscopically showed a metastatic carcinoma.

After operation progress was not satisfactory. X-ray treatments were tried but they caused marked nausea and vomiting and had to be discontinued. However, after some days the patient was able to be out of bed and was even able to shave himself.

During the next six weeks the patient grew steadily weaker, and he died January 1, 1935.

An autopsy showed that the original neoplasm had been in the head of the pancreas. It had encroached upon the duodenum and had caused an almost complete duodenal obstruction. It had also caused a complete obstruction of the common bile duct.

The fact that there had been no jaundice was explained as follows: at some time previous to his last illness, the patient had had a gall stone in the gall bladder. The stone had ulcerated into the duodenum and had established a sinus between the gall bladder and the duodenum. Bile

had drained through this sinus into the gastro-intestinal tract and was not dependent for a passageway on the common bile duct which was now occluded by the neoplasm. It had flowed freely into the duodenum distal to the obstruction. Thus, a simple mechanical readjustment by Nature explains the phenomena of a Carcinoma of the Head of the Pancreas without Jaundice.

SUMMARY

A patient with a very extensive and advanced carcinoma of the head of the pancreas, which was proved by operation and autopsy, did not develop jaundice. Failure to develop jaundice was explained by the fact that at some previous time a sinus had formed between the gall bladder and the duodenum, thus allowing free drainage of the gall bladder into the duodenum, independently of the common bile duct which had been occluded by a carcinoma.

Calcium Gluconate and Kaolin in the Treatment of Bacillary Dysentery*

By

BERNARD L. GREENE, M.D.

ELGIN, ILLINOIS
and

LOUIS H. BLOCK, M.D.

CHICAGO, ILLINOIS

OVER 1,000 cases of bacillary dysentery of Flexner type have been observed and treated by the authors in the past two and one-half years. In a small percentage the acute phase became chronic, indistinguishable clinically and proctoscopically from chronic ulcerative colitis, and as a rule persisted in spite of various treatments. In June, 1937, we decided to use the Haskell and Cantarow (1) method of calcium, kaolin and parathyroid extract treatment, first reported in 1931. However, before we were able to begin this study, our chronic cases had dwindled to two. We then proceeded to use this method in acute cases, modifying it by omitting belladonna and using our regular soft diet.

Since the patients under discussion are psychotic, it is usually impossible to obtain subjective information concerning the efficacy of treatment, and all conclusions were necessarily based upon objective findings. Fortunately, we had previously performed about four thousand proctoscopic examinations upon dysenteric cases and had observed the mucous membrane of the lower twenty-five centimeters of the large bowel in all phases of the disease. One of us, (L. H. B.) (2), had reported in a previous article that the infection apparently starts in the terminal ileum or cecum and travels downward, whereas when healing takes place it starts at the muco-cutaneous junction and always travels cephalad. Furthermore, the mucosal picture invariably corresponds to the clinical picture, i.e. the more severe the infection, the more marked the mucosal change. We have graded the proctoscopic mucosal picture into four groups: One plus (+) where there is a mild hyperemia and no blood vessels visible; two plus (++) where there is a moderate

hyperemia; three plus (+++) where there is an intense hyperemia and edema; and four plus (+++++) where the mucosa is intensely hyperemic, edematous and ulcerated. Healing, when it took place, always was a reverse of this order of involvement. A method was thus afforded to evaluate our results objectively according to the above groupings.

MODE OF ACTION

In developing the logic for the combined calcium and kaolin method of treatment used in this study it is best perhaps to consider certain aspects of bacillary dysentery in conjunction with the physiologic and

TABLE II

Comparison of the mortality and morbidity in the calcium and calcium-parathyroid groups

pharmacologic properties of the medicaments used. In the first place this disease is extremely debilitating and the patient suffers not only from toxemia, but from dehydration due to profuse bloody and mucous diarrhea as well. There is a diffuse inflammation of the colon that ultimately leads to necrosis and ulceration. The intestinal ulceration is so important that much study has been devoted to the mechanism of its production. Thus experimental and clinical evidence suggests that the primary intestinal lesions are due to a necrosing action of a thermostabile endotoxin, which after passing through the liver, is excreted from the blood vessels through the wall of the bowel into the lumen. Flexner (3) in 1906 first called attention to toxin excretion rather than the local action of the organism itself as the cause of ulcers.

An excess of calcium intake above the minimum required for the maintenance of physiologic function according to Sherman (4), Bernheim (5) and others makes the difference between a passable and buoyant state of health. Naturally, in the treatment of dysentery an improved state of health in the patient is of the greatest importance and for this general purpose alone calcium therapy is well justified. In addition, it alleviates symptoms of dysentery, promotes the healing of intestinal lesions and hastens the recovery of the

TABLE III

Analysis of mortality according to age group

Comparison in Mortality between the Calcium and Control Groups

Fig. 4

patient. By its sedative action calcium tends to allay the irritated state of the colon; further, it increases the resistance of cells to permeation by blood and lymph and thus helps to control bleeding from the ulcerated mucosa and prevents dehydration by reducing the exudation and transudation into the colon; calcium also stimulates immune processes of the body, protects liver tissue and function in toxic states, and is an antidote to toxic products, such as guanidine, generated as a result of tissue injury. The influence of intensive calcium therapy in overcoming allergic reactions has received much comment in the literature by various investigators and recently Silverman (6) has reported certain cases of bacillary dysentery that presented symptoms due to specific protein hypersensitiveness. Thus calcium has a number of physiologic and pharmacologic properties and the combined effect of some, if not all, of these apparently accounts for the benefit derived from calcium therapy in dysentery.

The literature dealing with diseases of the intestinal tract reveals the beneficial use of kaolin (China clay, bolus alba, purified aluminum silicate). Kaolin has been successfully used for centuries in the Orient. It was however, during the Balkan epidemic of cholera in the Balkan War in 1913, that Stump's bolus treatment (bolus alba) was tried at Nish by Kulme with remarkable results. Later, Walker (7) and Braasfladt (8) in 1919 used it extensively in the dysenteries in China. Kaolin is an inert powder possessing tre-

Shaded columns represent Calcium Group

Fig 5

showed some beneficial effect over the same period of time. However, the patients receiving the combination by mouth showed a higher percentage of improvement. The next procedure included oral calcium and kaolin plus intravenous or intramuscular injections of calcium glucono-galactogluconate* in 10% and 20% concentrations which are made possible by the high degree of solubility of this new salt.

Fig. 1 showed the marked decrease in the average morbidity when the calcium injected was given in 20 per cent solution, twice daily.

The last procedure consisted in the oral administration of calcium and kaolin, plus injections of calcium complemented by subcutaneous injections of parathyroid extract in a group of thirteen cases. Although the results were somewhat better than in the fourth procedure, (see Fig. 2) the added cost in our opinion did not justify its use in the remaining cases.

The dosage we are now using and the one that is giving us the best results is the intravenous or intramuscular injection of 10 cc. of 20 per cent calcium glucono-galactogluconate twice daily, complemented by two drams each of kaolin and calcium gluconate with or without an equal amount of Cal-C-Malt given every two hours orally.

RESULTS

From the months of July to October, 1937, we had 135 cases of acute bacillary dysentery. Seventy-five of these were used as a control and received no medication whatsoever, whereas 60 received calcium in various combinations.

An analysis of our cases revealed a great disparity

Comparison of Morbidity in the Calcium and Control Groups

Shaded columns represent the Calcium Cases

Fig. 6

mendous surface area and high adsorptive ability. Braasfladt (8), in a comprehensive study of the effect of kaolin on the intestinal flora in normal and pathological conditions, concluded that it carries down large numbers of bacteria from fluid media, if kept in motion; and it neutralizes various pathologic bacterial toxins; that when administered orally over a period of ten to thirty days in daily doses of one to two ounces, it changes the intestinal flora of human beings from a predominantly proteolytic to an aciduric type; (incidentally an editorial, J. A. M. A., November 13, 1937, commented upon the recent study of Eppwright, Valley and Smith, who showed the value of calcium and phosphorous in producing an increase in aciduric organisms). Walker (7) in discussing the rationale of kaolin concluded that its action is twofold: mechanical, by forming an adherent coating to the wall of the bowel, and by enclosing and carrying with it a very large number of bacilli; and, adsorptive, by adsorbing toxins. He further states that the layers of this inert substance on the walls of the intestinal tract act as a filter bed against effete material.

ADMINISTRATION

Our method of administration and the best combination of calcium and kaolin was arrived at by trial and error. First, calcium and kaolin were given separately, and then in combination. At the end of one week's observation, only one patient out of the ten that received calcium orally showed any improvement, whereas two out of ten that received kaolin by mouth

in the mortality of the two groups. The control group showed a mortality of twenty-four per cent as compared with seven per cent in the group treated with calcium.

We have analyzed our results according to the severity of the infection, believing that by doing so, we should have a better comparison. Fig. 4 compares the mortality as to severity of the disease, giving the number of cases in each grouping. Fig. 5 gives the percentage of deaths in each grouping. It will be noted that the death rate decreased 50 per cent by the use of calcium in the "intense" (+++) group, while in the ulcerated (++++) group, the mortality was 58 per cent, as compared with 5 per cent in the calcium group. An analysis of the deaths according to age groups further showed that the decrease was more marked in the 60 to 80 year group (see Fig. 3). An interesting observation was the decrease in the morbidity (the average number of days of hospitalization) of patients receiving calcium (see Fig. 6). The more rational patients stated there was a marked recession of abdominal cramps as soon as the intravenous injection was given. Some complained of a sensation of intense body heat following the injection. Over 900 injections of calcium were given without any local reaction or pain.

CONCLUSIONS

1. In sixty cases of bacillary dysentery the combined calcium and kaolin method of treatment herein described reduced the mortality by 50% to 75% depending upon the severity of the infection.

2. The period of hospitalization was reduced, but not notably.

3. The best results were obtained with intravenous or intramuscular injections of calcium gluconate supplemented by oral dosage with calcium gluconate and kaolin.

4. Parathyroid extract has but slight value in the intensification of calcium effects and its high cost does not warrant its use.

5. While the detailed action of the calcium and kaolin treatment used cannot be wholly explained, nevertheless, it seems entirely logical that the beneficial effects obtained are due to a combination of several well known properties of both substances.

6. Combined treatment with calcium and kaolin is more satisfactory than therapy with either of these medicaments used alone.

7. The above described therapeutic method is not offered as a specific but as a valuable adjunct to other proved medical measures.

Human Autonomic Pharmacology

XVII. The Effect of Acetyl-Beta-Methylcholine Chloride on the Gall Bladder*

By

PURCELL G. SCHUBE, M.D., ABRAHAM MYERSON, M.D.

and

RUTH LAMBERT, A.B.

BOSTON, MASSACHUSETTS

ACETYL-BETA-METHYLCHOLINE chloride (mecholy) is a choline compound closely related to acetylcholine. In physiologic research and in therapeutics, it has to a large extent replaced this latter drug because it is more nearly a total parasympathetic stimulant. While the general effects of acetylcholine include a parasympathetic effect with the inhibition of cardiac action and an increase of intestinal tonus, a vasodilating action, and a nicotine-like effect causing a rise in blood pressure when the other actions have been abolished, acetyl-beta-methylcholine, although it is a parasympathetic stimulant and causes a dilatation

of the peripheral blood vessels, has no nicotine-like effect. The general physiologic actions of acetyl-beta-methylcholine are (a) marked flushing of the skin extending over the face, chest, and upper part of the abdomen; (b) increased pulse rate; (c) a deeper and slower respiratory cycle; (d) a marked drop in blood pressure; (e) marked salivation; (f) marked lacrimation; (g) profuse alkaline diaphoresis; (h) slight cyanosis at the tips of the extremities with a drop in the surface temperature; (i) diuresis in certain persons; (j) occasional substernal pressure; (k) changes in electrocardiogram with temporary inversion of T waves in one or more leads; (l) increased intestinal tonus, peristalsis, and defecation rate. To

*From the Research Division of the Boston State Hospital, Boston, Mass., aided by grants from the Commonwealth of Massachusetts, The Rockefeller Foundation, and the Milton Fund.

the best of our knowledge there are no studies upon the effect of this drug upon this viscus. It is the purpose of this paper to present such a study.

METHOD

The patients in this study were all mentally ill but physically normal. All of them were males with an age range of from 22 to 40 years. Each patient was used as a control on himself and on the entire group.

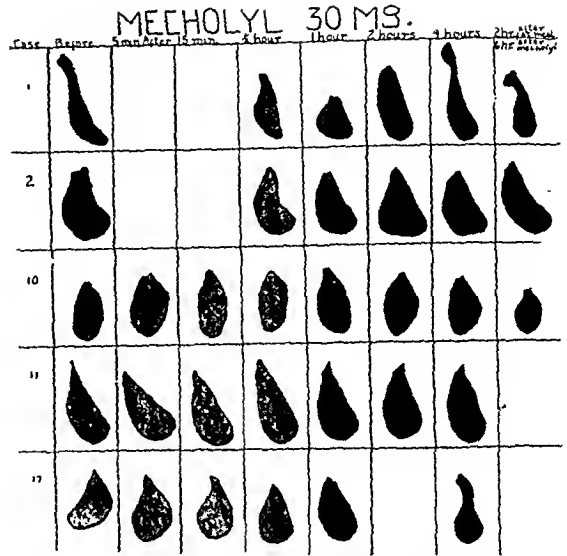

Control Study. Before the drug study was started, each patient was given a gall bladder dye test to determine the size and rate of emptying of the gall bladder. The night before the test the patient received a light meal, which consisted of dry toast, tea and sugar. One hour later he was given the gall bladder dye, tetraiodo-phenolphthalein sodium orally. The following morning after a fast of at least 15 hours, X-ray films were taken of the gall bladder region. He was then given a meal rich in fat, which con-

sisted of two slices of white bread thickly spread with butter, and two glasses of a milk and cream mixture into which had been beaten four raw eggs. After lapses of from 1 to 2 hours, X-ray films were again taken. Only those individuals were used in whom there was either a marked diminution or complete absence of the gall bladder shadow on the X-ray films that had been taken after the fatty meal. This method of dye administration and type of meal were used throughout the work.

Acetyl-beta-methylcholine study. Group 1. In this series the patient was given 30 mg. of meeholyl subcutaneously after the initial X-ray films of the dye-filled gall bladder had been taken. Two hours after the administration of the drug films were again taken, and the patient was immediately given the fatty meal. The films were again repeated two hours later.

Group 2. In this series after initial X-ray films had been taken, the patient was given 30 mg. of meeholyl subcutaneously, and subsequent X-ray studies were made

5, 15 and 30 minutes, 1, 2 and 4 hours after the drug had been administered. Each patient was then given the fatty meal and the films repeated in 2 hours.

RESULTS

Charts 1 and 2 are tracings of gall bladder shadows as visualized on the X-ray films of the patients in Groups 1 and 2 respectively.

Group 1. The effect of meeholyl on the dye-filled gall bladder was studied in these patients before the administration of the fatty meal. The X-ray films that were taken 2 hours after the drug had been given show little, if any, change in the size of the gall bladder shadow. In Cases 6 and 8 there was a slight increase and in Case 7 a decrease in the size of the shadow. The fatty meal was given to the patients and subsequent films, taken two hours later, showed a gall bladder shadow in every instance. In Case 6 the gall bladder shadow had increased in size.

Group 2. In this series of cases the effect of meeholyl on the dye-filled gall bladder was studied at frequent intervals over a 4 hour period before the administration of the fatty meal. These films, taken at 5, 15 and 30 minutes, 1, 2 and 4 hour intervals after the administration of the drug, showed no important changes in the size of the gall bladder shadows. The fatty meal was given to each patient 4 hours after the drug had been administered, and subsequent films showed an absence of the gall bladder shadow in only two cases.

DISCUSSION

The motor innervation of the gall bladder is unquestionably autonomic. Mann (1) in 1924 after reviewing the older literature concluded that the parasympathetic and sympathetic nerves to the gall bladder each carry both motor and inhibitory fibers, but that the parasympathetic was predominantly motor and the sympathetic inhibitory. More recent literature (2, 3, 4, 5, 6) on the cat and dog indicates that parasympathetic stimulation has little effect on the gall bladder as measured by evacuation. Whitaker (5) filled the gall bladder of the dog and cat with iodized oil and stimulated one vagus in the neck centrally and peripherally after recovery from anes-

thesia without observing evacuation. The animals evacuated later after a fat meal. Crandall (3) using the same method, stimulated the vagus just above the diaphragm and failed to obtain emptying. The gall bladder evacuated after a fat meal. Ivy (7) who has made many observations on the physiology of the gall bladder supports the conclusions of Mann. Westphal (8), using the guinea pig, found that weak stimulation of the vagus produced contraction and evacuation of the gall bladder and that this response was augmented by previous splanchnic section. Section of the vagus was without much effect. Splanchnic stimulation caused a relaxation of the gall bladder. When both vagi and the sympathetic nerves were sectioned, the motility was normal. On the other hand Dubois and Kistler (9) and Burget and Brocklehurst (10), failed to obtain evacuation of the gall bladder of the guinea pig after vagus stimulation. Ivy (7) states that in addition to the autonomic innervation of the gall bladder described there must exist for proper emptying a reciprocal innervation between the gall bladder and the sphincter of Oddi, i.e., when the gall bladder contracts, the sphincter of Oddi must relax. A large amount of experimental work which would tend to establish such innervation has been evaluated by him.

It would appear that the bulk of the experimental work on the motor innervation of the gall bladder indicates that parasympathetic stimulation does not produce an evacuation of the gall bladder. This being so it might be anticipated that mecholyl, a parasympathetic stimulant, would not produce an evacuation of the gall bladder. Such an anticipation would be strengthened by work with acetyl choline. The isolated gall bladder of dogs and guinea pigs has been observed to contract quickly and markedly following the application of this drug (11, 12, 13). Wood (14), using biliary fistula dogs has observed a flow of dark bile after the injection of acetyl choline, but when he placed a balloon in the gall bladder, he failed to obtain evidence of contraction. Voegtlin and Ivy (15), could obtain no evidence of contraction in the dogs' gall bladders after the injection of acetyl choline.

In our work the above expectation and the work on acetyl choline was further substantiated. As has been shown, in no instance did the gall bladder empty following the administration of acetyl-beta-methylcholine chloride (mecholyl). In addition to this mecholyl apparently delayed the emptying of the gall bladder after a fat meal. This delay was definite and observed in a sufficient number of cases to eliminate chance occurrence. In control studies performed upon the same patients no such delay was observed. Such an observation can mean only one thing, i.e., that mecholyl in addition to acting as a parasympathetic stimulant on the gall bladder per se also sets in motion another series of events which makes the gall bladder incapable of emptying after the administration of a fat meal. The actual mechanisms producing such inhibition are at the present unknown.

Ivy (7), in an attempt to evaluate the various factors concerned in gall bladder evacuation states: "In the relatively rapid type of evacuation of the gall bladder of man and dog, which occurs after the ingestion of a meal of egg yolk and cream, or fat, the evidence shows that the chief factor concerned is a

rise in intra-gall bladder pressure. This rise is due primarily to a more or less sustained tonic contraction of the musculature. The contraction is excited in part by a hormone (cholecystokinin) and by reflex nervous mechanism (cephalic and gastro-intestinal). The sphincter of Oddi and the duodenal musculature promote evacuation by relaxing and permitting bile to be expelled by the contracting gall bladder. The evidence shows that reciprocal functional relationship exists between the gall bladder and choledochoduodenal mechanism; but whether this relationship is causal is an open question. The evidence also shows that duodenal peristalses are not essential for, but assist evacuation. Peristalses may act by exerting a milking action on the intramural portion of the common duct. There probably exists some unknown intrinsic correlation between the sphincter of Oddi and the duodenal musculature, so that when the duodenum relaxes before an advancing wave of contraction, the sphincter relaxes. The evidence indicates that elastic recoil, attributable to both the elastic and muscular tunie of the gall bladder, may in the presence of 'high' intragall bladder pressure and a decrease in intramural resistance cause some evacuation. The dilution of bladder bile by hepatic bile, as determined by changing intramural resistance, the secretory pressure of the liver, and the phases of gall bladder contraction are concerned in the final or complete renewal of the contents of the gall bladder, or in the complete disappearance of the cholecystographic shadow."

In addition to this there exists a pertinent literature on the relationship of gastric acidity (16, 17, 18, 19, 20) to gall bladder evacuation and mobility (21, 22, 23, 24, 25, 26) which cannot be ignored. In this respect it has been demonstrated by us (27) that mecholyl definitely increases gastro-intestinal tone. Whether one of these factors is in any way responsible for the phenomena observed in the gall bladder or whether they are all the result of some fundamental chemical change such as is being observed in this laboratory in the tissue esterases is unknown. In any attempt to explain the inhibiting effect which mecholyl has upon the evacuation of the gall bladder all of these factors must be taken into consideration. In this paper this is quite impossible and impracticable, and we prefer to await the results of further studies which we have in progress to assist us in this respect.

Clinically, however, this work would seem to indicate that (a) there is no contraindication to the use of mecholyl in spastic gall bladder disease or in cholelithiasis; (b) mecholyl cannot be given to individuals who are having roentgenological gall bladder studies to determine the normal rate of emptying; and (c) emptying of the gall bladder by a fat meal can be prevented by the administration of mecholyl.

SUMMARY

A study of the effect of acetyl-beta-methylcholine chloride (mecholyl) on the gall bladder is presented.

It has been demonstrated that mecholyl has practically no effect upon the size and shape of the gall bladder, but that this drug in the majority of cases very definitely inhibits the emptying of the gall bladder following the ingestion of a fat meal.

Digestion and Absorption in a Man With Three Feet of Small Intestine

By

EDWARD S. WEST, JOHN R. MONTAGUE

and

FREDERICK R. JUDY*

PORTLAND, OREGON

DURING the summer of 1935 the writers had the unusual opportunity of studying digestion and absorption in a patient† of the U. S. Veterans Hospital, who, as a result of five resections at intervals over a period of eleven years, retained some three feet of small intestine (34 inches according to the surgeon's measurements). Less than a foot of jejunum remained. The last resection was done in 1933. He was operated on for intestinal obstruction in 1930 and 1933. Shortly after the latter operation severe diarrhea and tetany supervened necessitating calcium and Vitamine D therapy. An exploratory laparotomy was performed in March, 1935, and the small intestine found to be dilated and hypertrophied almost to the size of a normal large intestine. The lacteals showed unusually distinctly. The ileocecal valve appeared normal. There were some soft enlarged glands about 8 inches above it. There were relatively few adhesions and the entire intestinal tract appeared relatively free from disease with the exception of the dilatation and hypertrophy of the small intestine which the surgeon considered to be compensatory to its shortness.

When the patient came to the attention of one of us (M) March 30, 1935, he appeared as a fairly well developed man of 40 years, 5 feet 8 inches tall, in poor nutrition, and moderately cyanotic. The most note-

worthy symptoms were those associated with tetany. All reflexes were greatly exaggerated. The abdomen was quite uniformly distended and tympanitic.

TABLE I
Blood Ca and P on subject H

Date	Mg. Ca	Mg. P	Remarks
4-5-'35	6.5	—	In typical tetany.
4-10-'35	5.6	4.0	45 grains Ca gluconate + 5 minims viosterol t. i. d. beginning 4-11-'35.
4-16-'35	6.2	—	
4-17-'35	6.1	3.3	
4-24-'35	6.9	3.1	90 grains Ca gluconate beginning 4-20-'35.
5-8-'35	6.5	3.7	135 grains Ca gluconate 5-2-'35. Increased to 165 grains 5-9-'35.
5-15-'35	7.0	—	
5-27-'35	6.9	—	Viosterol increased to 10 minims t. i. d. 5-27-'35.
6-4-'35	8.7	—	
6-12-'35	7.6	—	
6-20-'35	8.0	—	Discharged from hospital 6-25-'35. Tetany relieved.
8-1-'35	9.2	—	Able to do light work.
10-12-'35	9.2	—	

*From the Departments of Biochemistry and Medicine, University of Oregon Medical School, Portland, Oregon.

†The patient apparently suffered from regional ileitis.

*Calculated on the basis of 4 Cals. per gm. for carbohydrate and protein and 9 Cals. per gm. for fat.

The treatment given was designed to combat tetany and consisted in the oral administration of calcium gluconate and Vitamine D (viosterol). Table I gives data relative to blood Ca and P of the patient during the period of observation.

The patient was exceedingly temperamental and insisted upon choosing his foods "a la carte" and it was only upon agreeing to let him do this that he agreed

calcium, and phosphorous contents for each meal were calculated from tables of food values. The patient received 165 grains of calcium gluconate daily during the experimental period. The calcium equivalent of this was added to the food calcium in calculating the total calcium intake. The stools, which were frequent and copious, were collected, mixed with sulphuric acid, and made to constant volume for analysis. Urines

to serve as an experimental subject. Consequently, it was impossible to place him upon an accurately analyzed diet. Through the cooperation of the Hospital Dietician he was permitted to select his foods for each meal, which were then weighed and served. A representative dietary is shown in Table V. It contained very little non-utilizable carbohydrate. The subject ate four meals per day. The carbohydrate, protein, fat,

were preserved with toluene. The experimental period included seven consecutive days, June 17 to 24. The patient's weight increased from 130 to 131 pounds during the experimental period.

METHODS OF ANALYSIS

Urine and feces were digested according to Gerritz (1). Fecal calcium was determined in the digest by

This dietary was calculated as equivalent to about 268 gm. carbohydrate, 119 gm. protein and 151 gm. fat with a caloric value of 2207 calories.

the method of Shoal and Pedley (2) and urine calcium by the method of Kramer-Tisdall as modified by Clark-Collip (3). Fecal and urine phosphorous were determined in the digests by the Briggs' modification of the Bell-Doisy method (4). Nitrogen of feces and urine was determined by the Kjeldahl method and converted to protein equivalent in the usual way. The carbohydrate of feces was determined by hydrolyzing with 1 N H_2SO_4 (gently boiled under reflux for 5 hours), followed by defecation of the hydrolysate with $HgSO_4$ — $Fe_2(SO_4)_3$ — $BaCO_3$ (5), and estimation of the fermentable sugar in the filtrate using washed yeast and the Shaffer-Somogyi reagent No. 50 (6). Fermentable urine sugar was determined but the quantity was negligible. Total fat in the feces was estimated by the method of Saxon (7). The proportion of fatty acids to total fat was determined on three unpreserved fresh samples of feces and found to be 85, 81 and 86 per cent calculated as stearic acid.

Data obtained relative to food intake, excretion and balance are summarized in Tables II-IV. The figures of Table IV show that carbohydrate was excellently utilized, undoubtedly as well as by the normal individual. About 25 per cent of the protein was lost in the feces and 45 per cent of the fat. The fat excreted was, however, rather well digested since better than 80 per cent of the total fecal fat was found present as free fatty acids (calculated as stearic). This excessive excretion of fatty acids was undoubtedly in great part responsible for the large loss of Ca in the feces (as calcium soaps). In Table III the ratio of fecal Ca to fecal fat is seen to be remarkably constant for this type of experiment. Table II shows that the average daily intake of carbohydrate, protein, and fat was 265, 133, 169 grams respectively with a caloric value of 3109 Cals. Of this, on the average, he utilized about 262 grams of carbohydrate, 93 grams of protein, and 101 grams of fat with a total caloric value of 2287 Cals. He lost roughly 25 per cent of the caloric value of his food. Table I shows a progressive improvement in the blood calcium of the subject as a result of large doses of calcium gluconate and viosterol. During the period of the metabolism study he was in positive calcium and phosphorus balance and his blood calcium,

though somewhat low, was definitely improved. Undoubtedly a diet containing relatively more carbohydrate and less fat would have been advisable for the subject in promoting calcium absorption, but his personal likes and dislikes prevented this being tried.

The efficiency of the intestine in digesting and absorbing food materials is strikingly brought out in this subject with only 12-15 per cent of the normal length of small intestine remaining. To be sure the absorbing area of the intestine was greater than 12-15 per cent of normal because of hypertrophy, yet the food remained in contact with the absorbing surface for a much shorter time than normal because of the diarrheal condition. Apparently nature has indeed provided the human with a safe excess of small intestine. Fat absorption would appear to be the chief limiting factor necessitating anything like the normal length of small gut.

SUMMARY

Digestion and absorption in a man with three feet of small intestine has been studied over a seven day period.

The assimilation of carbohydrate was found to be normal.

About 25 per cent of the ingested protein and 45 per cent of the fat was lost in the feces representing roughly 25 per cent of the caloric value of the ingested food. The fecal fat contained a large proportion of free fatty acids indicating fairly satisfactory digestion of fat and poor absorption of fatty acids.

A high calcium and viosterol intake was necessary to keep the man in positive calcium balance. The large amount of fatty acids in the feces was probably chiefly responsible for the poor calcium absorption. The daily ratio of fecal calcium to fecal fat was remarkably constant which tends to support such an explanation.

The writers are indebted to Mr. Allen Priest, Dr. John Ramage and Miss Marlowe Dittebrandt for analytical aid, and to Dr. Paul I. Carter, Manager, Dr. R. W. Brace, Chief Medical Officer, and Misses Margaret Beach and Ella Larsh, Dieticians of the U. S. Veterans Hospital for their cooperation in making this study possible.

ADDENDA: The man has just been readmitted to the U. S. Veterans Hospital in a condition of tetany. Further studies are planned if possible.

Melanosia Coli in a Boy Aged Two and One-Half Years*

By

JOHN H. WILLARD, M.D.

and

THOMAS J. SHUTT, M.D.

PHILADELPHIA, PENNSYLVANIA

IN 1933 Bockus, Willard and Bank reviewed the literature on Melanosis Coli and presented a series of forty-one cases in which the use of anthracene laxatives (cascara, aloes, senna, rhubarb and frangula) apparently had some etiologic significance. Zobel and Susnow, 1935, reported seven cases of this condition in patients using anthracene laxatives. The following case report is of interest in this connection.

CASE REPORT

R. L., male, age two years and six months, was first seen on May 3, 1937. His mother stated that constipation had been a problem since birth. The birth weight was 8 pounds, 13½ ounces. Development had been normal. Breast feeding was stopped after three months, the artificial feedings being reinforced with fruit juices and cod liver oil. Vegetables were added at seven months. Because of constipation various lubricants and mild laxatives were used from time to time and enemas frequently were required. In November, 1936, Fluid Extract Cascara Sagrada, 5 to 15 drops daily, was prescribed and gradually increased to 15 drops three times daily. In February, 1937, a mixture containing Fluid Extract Cascara Sagrada, Tincture Belladonna and Elixir Lactopepsin was substituted. The dosage prescribed amounted to 10 drops of the fluid extract of cascara three times daily; this was increased to the equivalent of 20 drops after a few days and was continued until admission. Enemas were given frequently. For six months this patient had received cascara almost daily.

Examination revealed a well developed white boy who appeared nervous and irritable. The general examination was not noteworthy. Rectal examination showed good sphincter tone, proctostasis, and a dilated rectum. By sigmoidoscopy, after a cleansing enema, the typical brown pigmentation of Melanosis Coli was seen. The color was medium dark brown and showed the irregular yellow striae described by previous writers as producing a "toads back" appearance. This condition extended at least six inches above the anus, the highest point reached with the sigmoidoscope.

Barium enema Roentgen studies demonstrated a colon of average size without defects.

Laboratory studies: Blood count: erythrocytes 3,870,000; leucocytes 6,200; neutrophils 55%; lymphocytes 39%; monocytes 6%; hemoglobin 78%. Urinalysis essen-

tially negative. Fecal analysis: undigested food in excess, fatty acids, faint trace occult blood.

On May 10, 1937, a program was outlined which included a bland diet, bland bulk (Mucilose), mineral oil, adequate vitamins, and an antispasmodic laxative powder containing extract of belladonna, magnesium oxide, calcium lactate and kaolin. The response was immediate and no further enemas or additional laxatives were given. Two weeks later (5/24/37) the sigmoidoscopic picture was practically the same as on the first examination, but in five weeks from the beginning of treatment (6/14/37) the pigmentation had disappeared entirely leaving only a mild congestion of the rectal mucosa. The patient's appetite and disposition had improved. Subsequent examinations (8/23/37 and 2/8/38) revealed a normal rectal mucosa.

DISCUSSION

The case here presented supports the view that the anthracene group of laxatives can produce Melanosis Coli. For six months this boy had been given laxatives of this type. There is no suggestion of the administration of heavy metals such as mercury or bismuth, which have been reported as causing pigmentation of the bowel, nor is there any evidence of intestinal bleeding. The appearance of the mucosa of the rectum through the sigmoidoscope was identical to that of the cases previously reported. Evidence of proctostasis was also present.

A survey of the literature reveals that the youngest previously reported case is that of Henschen and Bergstrand, a boy of thirteen years whose history is not recorded.

SUMMARY

A case of Melanosis Coli occurring in a boy aged two and one-half years is recorded. No report of this condition in a patient of this age can be found in the literature. The laxative history supports the premise of Bockus, Willard and Bank that the use of anthracene laxatives can produce a pigmentation of the bowel indistinguishable from Melanosis Coli.

The Medical Treatment of Cholecystitis*

By

WILLIAM J. MALLORY, A.M., M.D.†

WASHINGTON, D. C.

THE frequency with which cholecystitis occurs and the serious character of its consequences merits the great attention which it has received.

This subject has already received so much attention from surgeons, pathologists, physiologists and clinicians that the vast accumulation of factual material is so great that evaluation and interpretation are difficult. This is true concerning experts in each domain of investigation.

TABLE I

In 1,650 cases presenting gastric symptoms, cause of dyspepsia was organic pathology of the gall bladder, in	52 per cent
Blackford and Dwyer (1)	
In 1,000 routine post mortem examinations, signs of chronic and healed cholecystitis in	300
Estimates 40 per cent of the adult population have disorders of the biliary system.	
Crump. (2)	
All laparotomies in one hospital, cholecystectomies	5 per cent

In recent years the preponderance of medical opinion, greatly influenced by surgeons and pathologists, has been increasingly in the direction of regarding the disease as surgical, maintaining that change in the gall bladder wall, with or without stones, is the essential lesion and that surgical removal of the gall bladder is the remedy of preference, more especially if stones are present. This opinion, however, is not accepted without some qualification.

One observer (3), calls attention to the fact that in about one-third of the operations for the relief of gall bladder disease no stones are found, and in 90 stoneless cases observed for three and one-half years after cholecystectomy, there was no improvement in 47 per cent of the cases.

Whipple (5) writes: "We believe that conservative therapy is preferable to surgery in the majority of cases of chronic cholecystitis unless there is positive evidence in the history of biliary colic and typical interval digestive disturbances, such as bloating and belching, plus corroborative X-ray evidence of gall stones, or nonvisualization of the gall bladder by cholecystography."

MacCarty (6) names the varieties, simple chronic catarrhal, chronic catarrhal with cholesterosis, chronic catarrhal with papaloma, and writes: "These occur separately or in combination; all three occur with or without stones. Despite the fact that these are the simplest forms or stages of the disease, they are nevertheless the most difficult to diagnose clinically and to treat, either medically or surgically, correctly. They

are those which are followed after surgical treatment by the most frequent unfavorable late sequelae; they are the forms of the disease about which there will always be the question whether they should be treated medically or by cholecystostomy or cholecystectomy."

Clearly, then, medical treatment of this disease requires consideration, and more especially because of the frequency with which cholecystitis is found to be associated with other diseases.

These figures compel us to consider diagnosis and differential diagnosis, which leads to the classification of cases into

1. Those in which medical treatment of cholecystitis is not applicable, because of coexisting disease necessarily requiring surgery.

TABLE II

Comparison of follow-up study on calculus and calculus series. (Kunath, Carl A. (4))

Number of cases reviewed	100	100
Typical Biliary Colic	56%	84%
Pathology of the Gall Bladder, normal	25%	1%
Post-operative course, stormy	17%	7%
Wound infections	8%	1
4 eviscerations		1%
Mortality	8%	2.4%
Cured or improved	69%	84%
Appendectomy	62%	65%
End Results		
Number available for study	85	83
Cured	26%	51%
Improved	43%	32%
Unimproved	22%	13%
Dead	8%	2%
Incisional Hernia reported	4.7%	12%

2. Those in which exist contraindications for surgery, but removable or remediable, and therefore requiring medical treatment.

3. A group requiring surgical treatment combined with medical treatment, that is, all so-called surgical cases.

4. The remaining group concerning which both surgeon and internist agree that medical management alone is indicated.

In some instances diagnosis of gall bladder disease is easy; in others it is difficult, and even when such disease is known to be present, it is often more difficult to determine the presence or absence of coexisting disease elsewhere, and also what part the latter is playing in the production of symptoms and morbidity. Such diagnosis and differential diagnosis will require

not only the history taken by some one who is familiar with the symptomatology of the diseases in question, but also examination of all of the useful methods and clinical observation of the patient over a period of

TABLE III

Gall bladder disease is associated with	
Appendicitis (7)	50 per cent
Cardiovascular disease (serious) (8)	63 per cent
Angina Pectoris (25 per cent having stones) (9)	25 per cent
Autopsies on diabetic patients over 25 years of age showed gall stones present in (10)	23 per cent
In cholelithiasis, common duct stones present in	18 per cent
In cholecystitis, stones present in	64.5 per cent

time while under controlled management and treatment; i.e., making a therapeutic test.

Having dealt with the problem of diagnosis and differential diagnosis, and disposed of Group No. 1, we now consider Group No. 2, namely, Cholecystic disease requiring surgery but also presenting contraindications which demand medical attention.

These may be dealt with under the heads of Age, Cardiac Disease, Renal Disease, Diabetes Mellitus, and Neuropsychiatric Conditions.

Age (11) in itself is not a contraindication of needed surgery in gall bladder disease, because physiologic age does not necessarily correspond to or parallel chronologic age. Every care should be taken in preoperative study and examination. Operation, anesthetic, and surgeon should be fitted to the patient. The aged, in my opinion, offer less prospect of readjustment on the physiologic level than they do to skillful and artful combination of medical and surgical treatment.

Cardiac Disease is often a contraindication of needed surgical treatment, but that this may be overcome is shown by Walters (11) who operated successfully on a patient 72 years of age, with generalized arteriosclerosis, some dilation of the aorta, and electrocardiographic evidence of recent coronary occlusion; on one, aged 53, with angina pectoris; and one, aged 59, with arteriosclerosis and electrocardiographic evidence of coronary sclerosis; also two cases of bundle branch block.

A. R. Barnes (9) states that approximately 25 per cent of the patients who had angina pectoris have associated cholelithiasis; consequently, the management of cholecystic disease in the presence of coronary sclerosis is a frequent problem, but that cholecystectomy skillfully performed can be tolerated by a patient who has any degree of coronary disease up to and including recent coronary thrombosis. Whenever possible, operation on such a patient should be postponed at least 90 days after acute occlusion, and then should be undertaken by choice only if compensation is satisfactorily established.

The decision whether a patient's symptoms are chiefly anginal or whether they are attributable to the gall bladder, sometimes can be settled only by cholecystectomy.

Surgical treatment of disease of the gall bladder may sometimes be undertaken with a view to improving associated heart disease, and this occasionally

occurs, but that result cannot be relied upon, as a rule.

However, Willis (12) found 39 per cent of a group of patients with chronic cholecystic disease had definite changes in the cardiovascular system, of which hypertensive heart disease and coronary sclerosis were the most common. Seventy-nine per cent of the group were subjected to cholecystectomy; 54 per cent were definitely improved with regard to cardiac symptoms. There was one post-operative death from cardiac disease.

The presence of auriculoventric block is, in general, a sign of a more serious degree of coronary sclerosis and the risk in such cases is distinctly greater, on the average, than it is in cases in which the electrocardiogram shows evidence of bundle branch block only; but this condition—bundle branch block, unattended by other evidence of serious heart disease, must not be allowed to stand in the way of necessary surgical procedure, if the cardiac compensation is satisfactory.

Renal disease is equally serious and more important as a contraindication of surgery of the gall bladder and bile passages, and is probably more frequently the cause of post-operative deaths than is heart disease, because it does not often manifest itself so obviously as heart disease does and, being latent, is therefore overlooked or underestimated as a danger.

Operations on the liver are especially apt to cast an unanticipated burden on the kidneys. The field of operation (gall bladder, bile passages and liver) is normally rich in bacteria and inevitable trauma, existing disease in the tissues, anesthetic, dehydration and fasting readily precipitate a syndrome of maximal gravity.

Interrelation between the liver and kidney has long been assumed and Pytel (13) seems to have demonstrated that certain phylogenetic, anatomic, physiologic and pathologic relationships of the liver and kidney point to an interdependence of the two organs.

He succeeded in demonstrating in his animal experiments that damage to the liver is followed by a definite syndrome, characterized clinically by oliguria, albumi-

TABLE IV

Pathological conditions in the right side which occur alone or in association with gall bladder disease may be erroneously diagnosed as gall bladder disease, and so treated

Urinary:	
	Stone in the right kidney or ureter.
	Nephroptosis—Dietl's Crises.
	Kinked or stricture ureter.
	Hydro-nephrosis.
	Hyper-nephroma.
	Renal tuberculosis.
Other General Conditions:	
	Angina Pectoris.
	Spinal Disease, Arthritis, Metastases and T. B.
	Tabes Dorsalis. Crises.
	Sickle cell anemia. Crises.
	Herpes Zoster.
	Appendicitis.
	Hemolytic Jaundice (stones present in 65% of cases).

nuria, hematuria, nitrogen retention, loss of weight, apathy, and in some cases, death. Pathologically there were areas of necrosis in the liver; in the kidney, stasis of blood in the vessels of the malpighian bodies; hemorrhages into Bowman's capsule, with cloudy swelling and degeneration of the epithelium of the convoluted tubules.

Five to 10 cc. of blood removed from a rabbit with an experimental "hepatorenal syndrome" and injected into a normal rabbit, produced the above described effects.

He assumes the existence of a toxic substance resulting from liver necrosis, circulating in the blood stream and exerting its influence particularly on the kidneys and, to a lesser extent, on other organs.

Clinically this syndrome occurs in diseases of the liver and bile passages, particularly in the post-operative period or following acute traumatic lesions of the liver.

Diabetes Mellitus (14) when not under control is a definite contraindication for major surgical procedure, more especially on the liver and bile passages. Unrecognized symptomless diabetes is especially a menace because operations, anesthetic, deprivation of food, and dehydration are so apt to induce acidosis with its abdominal rigidity, pain, nausea, vomiting and leucocytosis, and these conditions occurring in the onset of coma may not be recognized for what they are, but may be mistaken for some surgical post-operative complication. A blood chemistry is the most important laboratory examination that can be made in preparation for gall bladder surgery.

Diabetes can be easily controlled by well known methods to such an extent that a major operation can be performed with nearly as little risk as in a non-diabetic patient.

The hepatorenal syndrome can best be prevented or controlled by similar methods, possibly combined with transfusion.

In neuropsychiatric conditions the situation is more difficult to determine, but the decision with regard to operation certainly requires an individual judgment for each case.

Having disposed of the important group of cases in which medical treatment will modify or remove known contraindications to needed surgical treatment, there remains the much larger group, including all so-called surgical cases, and these should have the best possible pre-operative preparation and post-operative management.

It may be said that surgeons now recognize and meet this requirement. But it should be emphasized that the best statistics on gall bladder surgery come from those well organized hospitals in which there is skilled and uninhibited collaboration between a surgical staff and a medical staff, accustomed to working together, and in which the members recognize each other's problems, ability and limitations.

There now remains that group of cases in which surgical treatment is not definitely needed, that is, there is no evidence of stones, tumor, or obstruction, but presenting symptoms of functional dyspepsia, not relieved by measures directed to conditions found in the stomach and intestines.

This group usually have mild pain under the right ribs, flatulence and belching, as a rule not definitely associated with the digestive cycle. Roentgenologically they may show either a normally functioning gall

bladder, one poorly visualized, or not visualized. Some of this group will have even typical attacks of gall bladder colic, requiring hypodermic medication for relief. This colic in itself does not necessarily place them in the class for necessary surgical treatment.

That such a group may exist seems to be indicated by the post-operative studies in noncalculous cases (4).

It will be generally agreed that this limited group comprises a small percentage of all cholecystic disease. It is not so obvious that satisfactory results from medical treatment are further limited by conditions inherent in the physiology and biochemistry of the biliary system.

However, it will become clear that success will be greater if aims and methods are made to conform with what would seem reasonably possible in the light of physiologic relations and clinical experience.

What these possibilities and limitations are will be more apparent by a reference to the physiology and chemistry of the biliary system. Recent information derived from experimental surgery, physiology and pharmacology has given us a rational though limited basis for physiological, medical treatment, so that while there is a more definite basis for treatment, there are also equally definite limitations as to what we may hope to accomplish under the existing conditions. Therefore, before hopefully undertaking medical treatment of cholecystic disease as such, to the exclusion of surgery, it will be definitely helpful to review briefly the motor, secretory and chemical mechanisms concerned in this system.

Concerning infection the facts may be briefly summarized: The tissues of the gall bladder, bile passages, liver and adjacent lymph nodes are all the normal habitat of a variety of bacteria, arriving mainly through the blood stream, but also through the lymph channels from the upper respiratory system and the intestines (15). Infection also occurs by reverse peristalsis into the common duct.

The simple presence of these organisms in the tissues does not cause manifest disease. Another factor must be added. Furthermore, their presence in the bile stream does little or no harm and is of relatively little significance.

Many bacteriological studies have shown that the tissues are found to contain bacteria about twice as frequently as the bile (16), nor is their number in the bile at all proportionate to the degree of infection in the tissues.

But it has been demonstrated experimentally and clinically that under adverse conditions such as trauma, stasis, obstruction and perhaps some other conditions which we do not understand precisely, such as shock and impaired blood circulation, the dormant organisms may set up an acute fulminating process which may cause death, become subacute, chronic, or subside entirely.

However, infection is not only an evil in itself, but also acts indirectly to produce a secondary sequence of events.

Inflammation or irritation of the gall bladder is believed to increase the rate of absorption of bile salts by the wall of the gall bladder (17), and thereby reducing the solvent action of the bile, leads to the precipitation of cholesterol and the formation of gall stones, which in turn are apt to cause obstruction and another series of grave events.

Infection, therefore, should certainly be controlled by all means, medical or otherwise; but the medical man should recognize his limitations in this field.

The modes of approach to the prevention or eradication of infection would be prevention and removal of foci of infection in the upper respiratory passages, and hygiene of the bowel. That the latter bears a practical relation to functions of the gall bladder was shown by Lahey and Jordan (18), when it was demonstrated that in 44 per cent of 65 cases of cholecystitis also manifesting signs of colon irritability the gall bladder would fill normally after from five to ten days of bowel management, whereas with the same intravenous dye technique it had previously shown an absence of or inadequate filling. It should be needless to say that such hygiene requires a therapeutic approach based upon the normal and abnormal physiology of the digestive system, and cannot be accomplished simply by the use of laxatives and enemas.

The idea of treating cholecystic disease, including cholelithiasis, by influencing metabolism is very appealing because it suggests the possibility of intervention through the primary phases of pathogenesis.

A glance at what is known concerning the physiology of cholesterol and especially what is unknown, however, is somewhat discouraging.

Unfortunately, cholesterol (the essential part of most gall stones) of the bile does not vary with changes in the total blood cholesterol, nor is its concentration raised by increasing the cholesterol content of the diet (19).

The percentage of cholesterol in the bile of the gall bladder is a result of the absorption of water and salts through the gall bladder wall, which results in a concentration of from five to ten times that of the bile as it enters the gall bladder.

Furthermore, the ability of the bile to hold cholesterol in solution is dependent upon the concentration of bile salts. If the usual ratio of cholesterol: bile salts, which is 1 to 20, up to 1 to 30, for any reason falls as low as 1 to 13, precipitation of cholesterol occurs.

There is no evidence that the body, cholic acid, is derived from cholesterol; feeding the latter causes no increase in the production of bile salts. The precursors of cholic acids in the body are also unknown. The site of its origin is unknown, whether it is formed by hepatic epithelium or is merely brought pre-formed to the liver from other tissues.

That some is formed in the body is indicated by the fact that the bile salts continue to be discharged from a biliary fistula during long periods of starvation; that it is derived from food as well is shown by the increased excretion which follows the ingestion of protein material. So far as is known, the liver is the only situation where the conjugation of taurin or glycochol with cholic acid and the production of the respective bile acids can take place.

In pregnancy, which seems to increase the frequency of gall stones, it is not the hypercholesterolemia (which is not constant), but the normal ratio of cholesterol to cholesterol esters, which is altered. Alteration of this ratio has been considered as an index of liver disease (20 and 21).

If the gall bladder is removed (and presumably, if its function is destroyed by disease) and its acidifying function eliminated from the bile duct system, gall stones of varying composition can be formed at will

by the precipitation of calcium carbonate, which is normally held in solution in bile acid.

There is a further indirect influence exercised by an inflammatory exudate, rich in protein material derived from the blood, which carries an electric charge of opposite sign from that held by cholesterol, pigment, and inorganic constituents. It is believed that as a result of this physico-chemical regulation the deposition of cholesterol, combined in varying degree with other biliary constituents, is effected.

Since it has been shown that bile acids maintain cholesterol in solution and that when they are reduced in concentration, carbonates are precipitated (22), and that acid bile will bring about the dissolution of gall stones (23), it would appear that maintaining or increasing the acidity of the bile would prevent the formation of, or possibly bring about the dissolution of formed gall stones, but the oral administration of sodium dihydrogen phosphate, salicylic acid and glycolic acid, substances known to be eliminated partially by the biliary system, do not influence the pH of the bile (24).

Increasing cholesterol in the diet does not increase cholesterol in the bile. High blood cholesterol does not cause increased cholesterol in the bile. Hypercholesterolemia in itself cannot cause gall stone disease.

The hypercholesterolemia observed in cholecystitis is the result of primary changes in the liver, which is so frequently seen in association with gall stone disease.

The lowering of the cholesterol ester—total cholesterol ratio, which has been observed and assumed to bear a relation to the formation of gall stones, would be difficult to change by any method with which we are at present acquainted. There is some clinical, therapeutic and experimental evidence that the liver is the site of the formation of cholesterol esters and that the diminution of them is an index of hepatic insufficiency.

While the cholesterol esters are usually lowered in acute liver degeneration, in cholecystitis and cholelithiasis, with no obstruction, and no complicating infection of the biliary passages, the blood cholesterol figures are not significantly altered.

From what is known of the complexity of the metabolism of cholesterol, cholesterol esters, bile acids and bile salts, as well as from the great limitation of our knowledge, it appears that there is little prospect of intervening effectively by medical or dietetic measures to a degree that will modify the development or course of cholecystic disease or the formation of gall stones, which so frequently complicates the clinico-pathological picture.

Concerning stasis or complete obstruction, it will be recalled that in other systems, whether respiratory, circulatory, urinary, or gastro-intestinal, extensive severe lesions may be present for a long time with a minimal immediate menace, and relatively mild symptoms; but when stasis or obstruction occurs, the potent character of the symptoms and the malign consequences are directly in proportion to the suddenness of the onset and the degree of completeness with which obstruction is established. A similar series of events and consequences obtains in the biliary system.

Stasis is therefore of the greatest practical importance in the development of cholecystic disease and its complications, because it not only influences the chemical and metabolic functions but, by disturbing the

secretory and motor functions, it contributes markedly to the awakening of a latent, inactive infection to an active process in one of the most vital systems of the organism. This would be very discouraging if it were the whole story, but it is singularly fortunate that, complex though it is, the motor mechanism of the biliary system is the better understood and more amenable to therapeutic attack than are any of the other factors operating in cholecystic disease, and therefore offers the most encouraging field for medical intervention in its disturbed functions.

The complete stagnation of total obstruction does not enter into the discussion in formation of stones because if the obstruction is complete and the gall bladder tied off or functionless, the intraductal roses (300 millimeters of water or more), secretion of bile is suppressed, the ducts become distended with a characteristic fluid (white bile) containing no pigment, bile salts or cholesterol, and bearing practically no resemblance to bile; and no stones can be formed.

If the normal gall bladder is left in communication with the obstructed duct system, the sequence of events is entirely different. Biliary stasis then causes thick greenish bile to collect in the ducts and bladder as a result of the latter's concentrating activities, and the mucinous material which it secretes. After a lapse of weeks the inspissated bile develops an almost tarry consistency.

The functions of the ducts and gall bladder are antagonistic, the former tending to dilute, the latter, to concentrate the biliary fluid. The diluting is at first overbalanced by the concentrating action of the gall bladder, and when this remains in communication with the duct system the net result is a marked inspissation of the bile. There is, however, a tendency with time for the activity of the ducts to overcome that of the gall bladder as it becomes functionless, the biliary constituents disappear, and ultimately the normal contents of the system are entirely replaced by a thin simple secretion of the duct and mucinous material from the gall bladder, producing hydrox.

Stasis, partial or temporary, caused by inhibition of the normal flow of bile, may be produced, (1) by marked changes in the bile, such as thickening, or by partial occlusion of the common duct by a small stone or plug of mucus; or, (2) by change in the normal mechanism by which the gall bladder is evacuated, namely; simultaneous contraction of the gall bladder and relaxation of the sphincter of Oddi. (Spastic biliary dyssynergia (25)).

That such a clinical entity exists has been demonstrated by Best and Hicken (25). They observed roentgenologically and clinically a state of affairs in which there occurred colicky pains, demonstrable spasm of the sphincter of Oddi, with failure of evacuation of the contents of the common duct. Partial or complete relief of the symptoms—pain and colic—with demonstrated evacuation of the common duct, was obtained in several instances by the use of certain nonsurgical measures.

This demonstration provides a rational basis for the prevention and treatment of biliary stasis, and this is the rational approach to the medical treatment of chronic cholecystitis.

Empirical treatment of chronic cholecystitis once consisted in the administration of calomel and salts. Later it reached a degree of elaboration and refinement at the European Spas where a meticulous diet

was given, alkali waters were drunk and salines taken with benefit.

With the advent of biochemistry it was believed that high fat diets were deleterious, in that the sequence of events was cholesterolemia, increased elimination of cholesterol in the bile and precipitation of cholesterol, representing the essential steps in the pathogenesis of gall stones. Present knowledge does not sustain this point of view.

After Meltzer's observation on the evacuation of the gall bladder and the clinical work of Lyon and many others, medical drainage of the gall bladder and biliary system became established as a diagnostic and therapeutic measure, but Lyon has written (26) "Once the definitely chronic stage is reached, the final therapeutic cure is secured only by surgical procedure aided by adequate medical measures directed toward lowering operative mortality and lessening post-operative morbidity."

This statement should be borne in mind despite the favorable reports of this method of treatment.

Feldman and Morrison (27) report of 61 noncalculous, malfunctioning gall bladders, 21 were drained by the Lyon method at regular intervals; 18 were completely relieved of symptoms.

Bile salts have long been used in gall bladder disease. Rosenak and Kohlstaedt (28) treated 63 patients having disease of the gall bladder and liver with bile salts over a period of nine months; in 22 cases of proved lithiasis, pain was not satisfactorily removed by this method of treatment; however, better results were obtained in relief of constipation and digestive symptoms. The treatment was more successful in 16 patients with cholecystitis, without proof of the presence of stones. Pain was relieved in a large proportion of these, and marked improvement in digestive symptoms in all was most striking. In 25 patients with symptoms indicative of gall bladder dysfunction, but in whom positive evidence of actual disease may be lacking, very satisfactory results were obtained. When bile salts were discontinued temporarily in these patients, all symptoms returned. Similar results could not be obtained by means of dietary control alone or by means of cathartics.

Brown and Dolkart (29) used Keto-cholanic acids. They selected for study a group of 131 patients who had been observed and treated for upper abdominal distress for a varying length of time. Sixty-five of these showing Roentgenographic evidence of dysfunction with and without stones were accepted for a test of therapy.

Seven variations in the therapy were used, namely:

- (1) Hourly feedings of milk and cream as in ulcer, and antispasmodic.
- (2) Hourly feedings and Keto-cholanic acids.
- (3) Hourly feedings, Keto-cholanic acids and antispasmodic.
- (4) Bland diet and Keto-cholanic acids.
- (5) Bland diet, Keto-cholanic acids and antispasmodic.
- (6) Low fat, low cholesterol diet only.
- (7) Low fat, low cholesterol diet, Keto-cholanic acids and antispasmodics.

All patients were ambulant. The mixture of Keto-cholanic acids contained the oxidation products of all the natural bile acids found in human bile in the normal proportions. Administration was orally in the form of 3¼ grain tablets, one tablet three times a

day. In four patients in whom no improvement in visualization was observed following 60 days of this medication, the dose was doubled.

Two criteria for evaluation of the results of therapy were used: (1) Frequent cholecystographic evidence of improvement; (2) Subjective changes.

The most consistent subjective improvement occurred in those patients receiving the Keto-cholanic acids. In the majority of instances the subjective improvement was found to parallel the objective improvement as revealed by repeated cholecystographic examinations. The exceptions were found in those patients in whom large stones had been demonstrated. These manifested marked subjective improvement but little change could be observed Roentgenographically.

Following the dietary and Keto-cholanic acid therapy, some previously nonvisualized gall bladders were visualized, and filling defects due to stones were noted, which were not previously seen.

In a few cases in which stones were reported in the Graham-Cole test, they were not seen on succeeding visualizations. Three of the patients with nonvisualizing gall bladders had normally visualizing gall bladders after therapy.

In those patients who gave histories of frequent, repeated attacks of gall bladder colic, these attacks would decrease in frequency and severity and gradually disappear after approximately two weeks of therapy.

In three instances untoward results were obtained in hourly feedings of milk and cream and Keto-cholanic acids simultaneously. One patient had distress in the epigastrium and distention; these symptoms subsided after changing to a bland diet. In two patients typical attacks of colic occurred; one of these on hourly feedings of milk and cream and Keto-cholanic acids, had colic, a slight diarrhea and passed some granular material which was examined and found to be typical faceted cholesterol gall stones, 2 to 4 millimeters in diameter.

The authors' interpretation of these results is guarded, especially concerning Roentgenologic evidence of improvement, as this may be due to (1) actual increased activity of the gall bladder, due to improvement in the pathologic gall bladder wall; or (2) improved mechanical flow resulting from increased amount of bile from the liver.

The need for care in interpreting Roentgenological improvement is indicated by the observation of Lahey and Jordan (18) who found 40 per cent of 65 cases of cholecystitis also manifesting signs of colon irritability; the gall bladder would fill normally after 5 to 10 days of bowel management, whereas with the

same intravenous dye technique it had previously shown an absence or inadequate filling.

Clinically, the patients of Brown and Dolkart obtained relief, not obtainable by other methods of treatment.

Gradual introduction of the treatment is desirable if the patient has been on a much restricted diet. The authors consider failure to improve clinically as manifested by continued pain, jaundice, repeated colic after the foregoing management, a definite indication for surgical intervention. Although they included in their series all forms of pathologic changes, termed chronic cholecystitis, no case was referred for surgery.

From what has been stated in the discussion of stasis and the use of Keto-cholanic acids it would appear that a combination of choleretics and cholagogues with a bland diet and antispasmodics would afford means for the rational medical treatment of a selected group of chronic cholecystic disease. However, this group will be limited and it is well to bear in mind the limitations of the therapeutic methods available.

One can do no better than to quote from A. A. J. Kelly in "Osler's Modern Medicine" of thirty years ago. "The physician, however, in many cases, may lead his patient into a condition of virtual cure, that is, latency or sterility of the biliary tract; but he must recognize his limitations and by a judicious balancing of his abilities and limitations not subject his patient too long to a useless medical treatment when early surgical intervention may restore him to health, whereas delayed, it may not only add to the miseries of a miserable existence, but actually hasten final termination."

Under the title of "Medical Treatment of Cholecystic Disease," this paper has dealt with physiology, pathology, diagnosis and treatment intentionally, because facts now available indicate emphatically that we do the patient and the art of medicine an injury when we think of, and practice the treatment of "cholecystic disease." Treatment should comprehend "the patient with cholecystic disease." Surgical treatment should be constantly in the mind of the internist and medical management should be a part of all surgical cases. Medical treatment, at best, is limited to certain possibilities, and likewise, although the surgeon can remove stones and a diseased gall bladder, the operation does not remove conditions which caused the disease or the secondary effects of the disease which existed.

In conclusion, I should say, the field for medical treatment of cholecystic disease, as such, is small and stony, and although not entirely sterile, any growth that occurs is apt to be malignant.

Editorials

PERNICIOUS ANEMIA AND ACHLORHYDRIA

ONE often reads that achlorhydria can be found occasionally in cases of definite pernicious anemia. Alsted (1934) collected thirty-two such cases from the literature. It has been thought also that achlorhydria is usually present for years before pernicious anemia develops, but cases have been reported in which this was not the case.

To help settle these questions, Rozendaal and Washburn (*Ann. Int. Med.*, 11:1834-1837, 1938) received the records of 906 consecutive cases from the files of The Mayo Clinic in which a definite diagnosis of pernicious anemia was made, and found achlorhydria in all of them. This finding agrees with that of Sturgis (*Ann. Int. Med.*, 10:283-289, 1936) who studied 600 cases. In none of The Mayo Clinic cases was there a return of free hydrochloric acid following treatment for the anemia. Hurst (*Guy's Hosp. Rep.*, 80:244-247, 1930), however, has reported four cases in which the secretion returned following treatment for the gastritis.

In thirty-six of the cases at The Mayo Clinic a study of the gastric secretion had been made from two to twenty-one years prior to the onset of pernicious anemia. In almost every one of these cases the blood was studied at the first visit, and in only two cases was there a slight anemia. This was of the microcytic hypochromic type. In only two of the thirty-four cases was there any free acid in the stomach years before the pernicious anemia appeared. In these two cases the previous examination was made nineteen and seventeen years respectively prior to the onset of the anemia.

These two series of cases of Rozendaal and Washburn and Sturgis indicate, then, that the presence of free acid in the stomach of patients with apparent pernicious anemia should make a physician very distrustful of his diagnosis in regard to the nature of the anemia. It seems clear also that in all but a few cases the achlorhydria is due not to the anemia but to a condition probably hereditary and perhaps congenital, which long antedates the appearance of the anemia.

W. C. Alvarez, Rochester.

IRON IS NOT EXCRETED BY THE INTESTINAL MUCOSA

IT has been stated by many observers that several of the metals, and particularly salts of iron, are excreted by the mucosa of the colon. At the last meeting

of the American Society for Clinical Investigation, Stephen Maddock and Clark Heath (*Jour. Clin. Invest.*, 17:533, 1938) of Boston, reported some interesting and apparently decisive experiments in which they first grafted various parts of the digestive tract with their blood supply into the abdominal wall of the dog. Iron was then given, either by mouth or parenterally. Before and after giving the drug, bits of tissue from the exposed mucous membrane were snipped off, stained for iron, and studied histologically.

No definite increase in iron was found in the bits of tissue from the bowel of the animals given iron. At necropsy large amounts of iron were found in the liver and spleen, and smaller amounts in the kidney and skin, but none was found in the mucosa of the stomach, duodenum, ileum, cecum, or colon.

According to the investigators these findings agree with those of some other workers in the field of iron metabolism, all indicating that there is no appreciable excretion of iron by the intestinal mucosa.

W. C. Alvarez, Rochester.

THE SPIROCHETES OF THE GASTRIC MUCOSA

IT has long been known that spirochetes are to be found in the gastric glands of a large percentage of laboratory animals. They have been found in the dog, cat and rabbit. Curiously, they are commonly seen in the canaliculi which run up into the substance of the parietal, or acid-secreting cells of the stomach. Doenges (*Proc. Soc. Exper. Biol. and Med.*, 38:536-548, 1938) now reports the finding of spirochetes in the gastric glands and parietal cells of 100 per cent of some forty-three *Macacus rhesus* monkeys studied. Such spirochetes were not found in the glands of the intestinal mucosa.

Doenges studied also sections from 242 well preserved human stomachs removed at necropsy, and found spirochetes in 43 per cent. Usually only a few were found after considerable search, and large numbers were found in only eleven of the specimens.

It is possible, of course, that in some of these cases the spirochetes entered into the tissue during the agonal period or even after death. Someone now should look for them in material removed at operations on the stomach.

W. C. Alvarez, Rochester.

Book Reviews

Digestive Tract Pain: Diagnostic and Treatment. By Chester M. Jones, M.D. The Macmillan Company, New York, N. Y., 1938.

This small volume of 143 pages deals with pain and other similar sensations as referred to the alimentary tract, deals with it as a clinical symptom, as of diagnostic importance and discusses the physiological substrate underlying its creation in the body. But essentially the author utilizes an old but well recognized experimental method for his interpretation of the symptoms, namely such subjective and objective data as are obtained by distending each segment and part of the alimentary tract with an inflated balloon. A small balloon was swallowed to different levels of esophagus, stomach and small intestine, and it was inserted through colostomies, ileostomies and into the rectum. Clinical subjective tracings are tabulated, Pain, heartburn, fullness, distress, heat and cold recorded, and subjective sensations of distress are studied in their relationship to the body surfaces and to the various abdominal and thoracic segments.

The location of the origin of disturbance (the distended balloon) and the surface area of the pain are correlated and interpreted for each organ and for each segment of the alimentary tract. No profound attempt is made to cover all of the experimental, clinical and philosophical concepts and publications referring to the study of pain in the past. To do this would have occupied a volume in itself. Though due respect is given to the concepts of Head, Lennander, Mackenzie and others, the author prefers to rely on the clinical diagnosis as established in each case, and to study each particular individual by his own kymographic approach, utilizing his own physiological interpretation.

The most interesting part of the book is that which deals with the subjective symptoms of pain and heartburn at the various esophageal levels. While much of the work is a repetition of that of Hurst, and of the more recent study of Babby, the analyses of the subjective thoracic sensations and surface areas are very enlightening, particularly from a clinical viewpoint. Again, the references of pain originating in the various levels of the small intestine are timely and are accurately located. The new interest

in the various forms of granulomatous lesions of the small intestine, particularly the ileum, and the various forms of segmental colitis makes this chapter the more valuable. Unfortunately too many pain zones of the ileum, jejunum and colon coincide in general location. As in the case of Head zones, the areas demarcated by Jones often overlap and duplicate each other, so that clear-cut clinical conclusions as to the origin of a pain cannot be attained.

The book should be read and re-

read, and the careful conclusions in each individual case closely scrutinized. The author is a careful, honest clinician of established reputation. His case histories will bear close analysis and seem well established as to diagnosis. His conclusions, are, like the author himself, reserved, never overstated, and always scrupulously modest and honest. The volume can be heartily recommended for careful study by advanced students and clinicians who spend

their hours in the consulting room at the baffling problems of trying to correlate abdominal pain with the organ and the lesion from whence it originated.

B. B. Crohn.

Maribuana. By Robert P. Walton. J. B. Lippincott Company, Philadelphia, 223 pages, 1938.

As many physicians know, hashish or cannabis indica, long used in the East as an intoxicating drug, has invaded the United States and is becoming a big problem, particularly in the Southwest, where peddlers have been distributing cigarettes known as reefers, muggles, or goof butts, to

school children, negroes, prostitutes, and others.

The smoking of these drugged cigarettes by boys and girls appears to be widespread. It has become a new fad, and something must be done to stamp out a growing industry. Habituation leads, much as it does with opium, to the destruction of character and the ruination of nerves. The drug affects the whole nervous system. There are hallucinations, sometimes inordinate and senseless laughter, and a feeling that the subject is floating away. Sometimes the dreams are horrible nightmares, and sometimes the smoker develops an exaggerated irritability which leads

to violent rages. Cases are known in which the habitue ran amuck and committed murder.

Walton has made a most extensive study of the problem from every point of view, and his very interesting volume should be of great help to those who are struggling to stamp out the trade in this narcotic. The most distressing feature of the problem is that peddlers are reaching out to enslave the children in our schools.

Physicians will find the book very readable. The chapter containing the descriptions of the visions experienced by a number of able writers will be found particularly interesting.

Our Common Ailment. Constipation: Its cause and cure. By Harold Aaron. New York, Dodge Publishing Company, 192 pages, 1938.

Perhaps the commonest of those dysfunctions of the body that come with civilization is constipation. Because of it millions of men and women today are dosing themselves regularly with laxatives, purgatives, and indigestible oils and gums. Some who have the digestion of an ostrich get along fairly well; others who have a more sensitive intestine are in trouble all the time. We of the medical profession are not always very helpful. Too often we run to fads: the physician who has some favorite laxative prescribes it for every patient, and those physicians who now prescribe a rough diet or some mixture of gum and oil commonly threaten with dire disaster any patient who dares to use an enema or a mild laxative. Few physicians today seem to know or to face two facts: One, that the treatment for constipation must be fitted to the individual, and the other, that what works for a patient one week may not work at all the next week.

Under these circumstances, people need more help, and many need a book which will explain many things, answer many questions, and combat much false information and belief. Here at last is a book by a sane, well-informed writer who has supplied the three things so much desired. He tells of the causes of constipation and of the difference between the mythical high and low enemas. He shows up the buncombe in modern campaigns for alkalization of the body or for fastening on baby a lifetime purgative habit (she will cry for it); and it routs the boogies of autointoxication, spastic colitis, and ptosis.

Although written primarily for a lay audience, it is well worth reading by medical men and even by consulting gastro-enterologists. Many could profit from the lessons it teaches, and many would be much interested to learn facts about the composition of the various gummy substances and laxatives. Every young physician

RECENT ADVANCES IN THE SCIENCE OF NUTRITION

IV. Some Accomplishments of Vitamin D Research

● By 1932, many of the basic facts concerning Vitamin D had been clearly established (1). At that time, the International system of denoting vitamin D unitage had not been universally adopted. However, the antirachitic potencies of a wide variety of biological materials had already been explored; the need for standardization of assay methods was appreciated; the minimum requirement of infants and children for vitamin D had been estimated; and the probable "multiple" nature of the vitamin deficiency indicated. Since 1932, the importance of vitamin D in human nutrition and the challenge of the many unanswered questions regarding this factor have served to stimulate research both in the clinic and in the laboratory. It is of interest to note some of the outstanding advances made in our knowledge of vitamin D which the past six years have brought. It is now known that at least ten different steroid derivatives are capable of exhibiting the physiologic properties of vitamin D. Of these, only two may be considered of prime importance as far as practical application in human nutrition is concerned, namely, the activation products of ergosterol and 7-dehydro-cholesterol. The remaining forms are of considerable theoretical importance in that their identification has completely established the multiple nature of vitamin D (2). Further research has also defined more closely not only the vitamin D requirements of normal infants and children, but also of premature infants and those peculiarly susceptible to rickets. Apart from conditions of pregnancy and lactation, the possible reciprocal relationship between the two forms of vitamin D is still a matter of controversy. Your suggestions will determine the subject matter of future articles. This is the statement in this advertisement of the American Medical Association.

AMERICAN CAN COMPANY 230 Park Avenue, New York, N. Y.

It is in the formulation of basic diets for either infants or adults that commercially canned foods should prove especially valuable. Among the great variety of American canned foods are included special foods for use in child and infant feeding which, when properly supplemented or fortified, should meet the nutritive demands of those stages of life. For the normal human adult—whose diet hardly requires special supplementation—there are a large number of canned foods available which readily permit formulation of a varied diet of the so-called protective foods.

We want to make this series valuable to you, so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles. This is the statement in this advertisement of the American Medical Association.

starting out in practice should read this book.

We rejoice to find a man who writes of medical matters for the lay public using simple Anglo-Saxon speech and depending for his grip on his audience not on slapdash and efforts to be funny or clever, but on cramming his pages with information of interest and value.

The Diets of Olympic Athletes of the Past and Present (Die Ernährung der olympischen Kämpfer in Vergangenheit und Gegenwart). By Adolf Bickel. A booklet of 35 pages and 2 illustrations. Deutsche Verlagsgesellschaft M. B. H., Berlin, 1938.

The Relation of the Quality of the

Dietary Protein to the Course of the General Metabolism (Ueber die Beziehungen der Qualität des Nahrungseiwisses zum Ablauf des Betriebsstoffwechsels). By Adolf Bickel. Paper, 100 pages. Benno Schwabe & Co., Verlag, Basel, 1938.

The former of these two works is an address delivered by Bickel at the University of Athens; the second is a monograph published under the auspices of the Schweizerische Medizinische Wochenschrift. They contain some material of immediate interest to the student of nutrition; in addition, they suggest hypotheses that should inspire a great deal of further research. In view of the ideas con-

cerned, a somewhat detailed presentation seems desirable here, especially since the author's style frequently becomes so involved that few readers, whatever their linguistic accomplishments, will find it easy to go through all of the material in the original language.

Schenk's study of the diets of athletes who participated in the Olympic Games in Berlin in 1936 showed that lean meat was the central article of diet; it was commonly eaten rare, sometimes even raw. Bickel's thesis is that the instinctive preference of athletes for certain proteins results largely from a factor hitherto unrecognized in dietetics—a striking difference among the proteins in the way they affect metabolism. This factor is distinct from others now generally known, such as the completeness of the protein in essential amino acids. Though it so far eludes identification, it betrays itself in at least three ways: (1) the ratio of oxidizable material to total nitrogen in the urine, (2) the ratio of carbon to nitrogen in the urine, (3) the amount of glycogen stored in the liver. These are the three determinations upon which Bickel's work is based.

The two urinary ratios depend upon three chemical procedures. The first is the customary Kjeldahl procedure for nitrogen. The second is the determination of oxidizable material; the procedure consists in treating the sample with an excess of potassium iodate in sulphuric acid. This oxidizes a variety of urinary constituents; the amount of oxidation is measured by the amount of left-over iodate. This yields a figure called the Vakatsauerstoff, hereinafter abbreviated "V-O." The third procedure consists in determining the total carbon by oxidizing it in the wet way with a mixture of bichromate-sulphuric acid and silver bichromate, and absorbing the carbon dioxide. The figures for total nitrogen, total carbon, and Vakatsauerstoff yield two urinary quotients, C:N and V-O:N. The chemical significance of these ratios remains to be settled; the remarkable thing about them is the way they change when the type of protein is changed in a diet otherwise kept constant.

Bickel found that these ratios remained reasonably constant both in animals and in man if the diet was uniform. But if the diet alternated between normal and protein-free sharp differences resulted. In a given diet, if the casein was replaced with a casein modified by irradiation with gamma-rays from mesothorium, the C:N fell while the V-O:N, after some irregularities, went up strikingly. Various experiments were done on the substitution of amino acids for whole proteins; thus tyrosine was found to raise the V-O:N markedly

TRI-CALSATE

A POWERFUL NEUTRALIZER

causing no rebound in acidity

Tri-Calsate—the buffered neutral antacid—neutralizes gastric HCl in the treatment of peptic ulcer, hyperchlorhydria, heartburn, etc., without causing a rebound in acidity.

Maximum (Sippy) dosage can be maintained without harmful systemic effects. Non-toxic... non-irritating... palatable and economical. Available on Rx in 4½ oz. and 18 oz. bottles.

Write for trial package and complete literature today.

terology Says . . .

"The recent advances in gastro-enterology have been of such magnitude and distinction that they engender in us a just pride and renew our determination to press forward toward our goal of perfection."

Dr. Ernest H. Gaither, Baltimore, Md., in his address at Kansas City before the section on gastro-enterology and proctology of the A.M.A.

The American Journal of Digestive Diseases

- Now in its fourth year of publication—without alteration in its fixed principle of giving to the reading members of the medical profession the contributions of the best clinicians and investigators in the United States, Canada and Europe.
- So formulated, and edited by one of the most capable and select editorial groups in contemporary medical journalism, the Journal has made unusual progress during the comparatively short period of publication . . . today, the editorial office is constantly in receipt of very valuable manuscripts which collectively form a cross section of new gastro-enterological thought.
- The absence of "politics" from this set-up ensures to the reader an unbiased preliminary evaluation of submitted material by men pre-eminently qualified to judge the worth of MSS in the various sub-fields of this broad specialty.
- Meeting the growing difficulty of prompt publication, the Journal is constantly diminishing its back log of material by insistence more and more, as time goes on, upon the idea of BREVITY in writing.
- The American Journal of DIGESTIVE DISEASES is not only making friends but it is KEEPING friends. The renewal percentage each year and each month is a positive proof of the sound, month-by-month value of the publication, and it is recognized that this Journal provides today, as no other publication ever provided, a trustworthy postgraduate education in a field much more intricate and fascinating than has been generally supposed.
- Once upon a time gastro-enterology was generally regarded as a specialty contaminated by faddism and quackery, but the pioneers, many of whom are still living and active on this editorial board have lifted it to the level of a strictly ethical study—and the Journal is playing an important role in facilitating this important branch of medical practice.

An Open Letter to the Physicians of North America

Do you realize that 60 per cent of all symptoms in general practice arise from the digestive tract?

Many diseases are intrinsic, and many at a distance reflect their symptomatology with great facility in the alimentary canal . . .

Is diagnosis of digestive diseases easy?

Apparently not. The old rule of thumb—"appendix, ulcer, or gall bladder" is no longer useful. We are becoming gradually acquainted with the disorders and diseases of the colon and reducing this information to some semblance of order. Physiology, bacteriology, chemistry, parasitology, clinical observation, animal experimentation, roentgenology, nutrition, allergy and psychology are the organized methods of approach to a fuller knowledge of

digestive diseases. And there still lies beyond, the *dark continent* of the small intestine, concerning which so little is positively known.

To the scholar, what is offered by this Journal is indispensable.

To the man too busy to indulge his yen for applied research, may we say this—an hour a month with the American Journal of DIGESTIVE DISEASES will provide the key to *practical success* in this most important, difficult, but "treatable" field.

Spend \$6.00 for a year or \$10.00 for 2 years NOW. Join the increasing group of doctors who enjoy this periodical. The card below is attached for your use, and is postage free.

2 SIMPLE WAYS

of Preparing Palatable High Concentrations of KNOX GELATINE

PHYSICIANS are constantly asking us for formulae for the preparation of Knox Gelatine in a concentrated palatable form, useful in the dietary treatment of such conditions as muscle fatigability and gastric ulcer. Research on such formulae has shown these to be excellent.

"The Knox Milk Stir"

Place the contents of 4 envelopes of Knox Gelatine in an ordinary drinking glass. Add 4 ounces of cold milk and allow to soak for five minutes. Add 2 more ounces of milk and stir until thoroughly soaked. Then place glass in small cooking kettle of hot water until gelatine milk mixture is thoroughly dissolved. Add 2 more ounces of cold milk, which will bring the temperature to a satisfactory warm drink of about body heat. A tablespoonful of prune juice or a few drops of any bland flavor like vanilla may be added.

Total: 8 ounce liquid — about 250 calories

"The Knox Fruit Stir"

Place the contents of 2 envelopes of Knox Gelatine in an ordinary saucer or cereal dish. Add 8 tablespoonfuls of any desired fresh or canned fruit juice, such as grape juice. Let soak for five minutes and eat with teaspoon.

*Total: 4 ounce mixture —
about 100 calories*

They are ideal when frequent feedings and extra calories must meet adequately the level of nutritive requirement. Indicated to allay the pain in the gastric ulcer patient when given hourly. An adequate food adjunct both from the standpoint of easy digestibility or "low residue" in gastro-enteric dysfunction or intestinal stasis. Also of value for their high amino-acetic acid (glycine) content in dystrophic muscular conditions.

Why You Should Insist Upon Knox Sparkling Gelatine

Because Knox Gelatine is 85% protein in an easily digestible form—because it contains absolutely no sugar or other substances to cause gas or fermentation, Knox Gelatine should not be confused with factory-flavored, sugar-laden dessert powders. Knox is 100% pure U.S.P. gelatine. Knox Gelatine has been successfully used in the dietary of convalescents, anorexic, tubercular, diabetic, colitic, and aged patients.

Sample and useful Dietary Booklets on request. Write Dept. 475

KNOX GELATINE LABORATORIES JOHNSTOWN, NEW YORK

while lowering the C:N. In other experiments, various amino acids were administered not only by mouth but also subcutaneously.

In particular, a very extensive experiment was done in which diets containing casein, as a standard, were compared with other diets in which everything was the same except the protein. In those cases in which casein was compared with complex protein-containing foods like potatoes, the control casein diet was mixed with potato starch, etc., in such proportions as to make it reasonably certain that the total nitrogen, carbohydrate, fiber, and calories in the two diets were equal. The only

difference between control and test diet, then, was in the type of protein. The results showed that it was possible to arrange the various proteins on a linear scale according to their effects on the urinary quotients and liver glycogen. At one end of the scale came gelatine, wheat gluten, and edestin, with low urinary quotients and low liver glycogens; at the opposite extreme were the proteins of soy beans, green beans, carrots, potatoes and oats.

Evidently this makes possible a new dietary classification of proteins, a classification not identical with others based on high or low glucose equivalent, specific dynamic action,

amino acid content, and plant or animal origin. It also suggests new possibilities for the control of the general direction of body metabolism by prescribing the type of protein to be eaten. It should also challenge investigation of the exact chemical nature of the metabolic processes reflected in the new urinary quotients.

Frederic T. Jung, Chicago.

CONNOTATIONS

H. J. SIMS, M.D.

Denver, Colorado

Albucasis, an Arabian physician residing in Spain, during the eleventh century recorded the first case of extra-uterine pregnancy.

Gibson made the first report of a diseased gall bladder in a male child 12 years of age, in 1722. The diagnosis was made at autopsy.

The yellow color of rhubarb was once thought to contain the active ingredients capable of exciting the flow of bile.

The humoral theory of disease was formulated by Philolaos of Croton. He based his work on that of Anaxagoras. Hippocrates agreed with Anaxagoras and believed any disturbance of the equilibrium of these humors resulted in disease.

The idea of mothers chewing for infants dates back to antiquity. Whether the idea developed as a supplementary feeding or whether it replaced milk is not known. The writer has seen mothers chew potatoes and other articles of soft food and then force the bolus within an infant's mouth. According to Vallembert, Galen prescribed bread soaked in broth or soups for nurslings. The same author refers to a mixture of flour or bread cooked in water known as pap and then mixed with milk as panada. He dated the beginning of the use of pap in the year 1465. The mixture was first chewed by the mother or nurse and given to the infant. This method of feeding continued for over a century. Ettmuller in 1698 and Astruc in 1746 questioned the advisability of such feedings and yet as late as 1830 special pewter spoons were manufactured for the purpose of controlled feedings.

It is not known in general that President Cleveland suffered from a sarcoma of the upper jaw. In the year 1893, he secretly entered a private yacht and underwent an operation for resection of a portion of the upper jaw. An artificial vulcanized rubber jaw was made to fit into the defect. This artefact was so well adapted that no apparent defect in speech was noticed.

Anatomical dissections by Hippo-

Choosing a Happy Medium . . .

EXICOL

(Oleic Acid and Bile Salts)

The most recent researches* again emphasize the marked fat-intolerance displayed by patients suffering from gall bladder disease, and the satisfactory therapeutic results on a low fat diet and bile salts. Contrary to recent advocates of high fat therapy, it is pointed out that overstimulation of the gall bladder, produced by such high fat diets is undesirable.

Exicol, containing a small quantity of fatty acid and bile salts, offers a solution to the controversial problem of biliary tract therapy. It is the most rational therapeutic agent in biliary disorders because—

1. It stimulates mild gall bladder contractions due to the fatty acid.
2. Increases bile secretion from 100 to 200% ** due to synergistic action of oleic acid and bile salts.
3. Makes high fat diets unnecessary.
4. Exicol is most effective as an aid in the treatment of chronic cholecystitis, biliary insufficiency and other non-surgical as well as post-surgical biliary tract disorders.

FLUID BULK and COLONIC "BATH" with Undiffused Solution

The fluid taken with Sal Hepatica is only partially absorbed. Thus, Sal Hepatica provides safe *liquid bulk*—far peristaltic motility. The intestinal tract is water-lubricated and gently flushed.

Sal Hepatica aids the gastro-intestinal tract throughout its entire length. Mineral alkalines offset excessive gastric acidity without interfering with gastric function. The flow of bile into the duodenum is increased through cholagogic and choleretic action.

Sal Hepatica simulates the action of famous mineral spring waters. It makes a zestful, effervescent drink. Samples and literature available upon request.

SAL HEPATICA Flushes the Intestinal Tract and Aids Nature to Combat Gastric Acidity

BRISTOL-MYERS CO., 19-NN West 50th St., New York, N.Y.

crates were likely limited to the Barbary Ape and to domestic animals although occasionally he must have observed abdominal organs of man at the time of embalming. Dissections of the human body through religious teachings were not permitted. A dead body was thought contemptible and yet it was too sacred to be subjected to whimsical curiosity from which nothing could be gained. His concepts of the aqueduct of Sylvius, the hypophysis, cerebral nerves, sympathetic ganglia, and the third and fourth ventricles of the brain were gained from dissection of the brain of oxen. He stated that the uterus contained

two compartments. The right testicle and the right chamber of the uterus were capable of producing a male child. It is evident that he had not observed a human uterus.

Galen continued to teach the humoral theory of Hippocrates. As long as the humors existed in proper relation to each other, health was maintained. If they became diminished or thickened, or were retained in some remote area in the body, disease was manifested. In the summer months, yellow bile predominated; during the winter months, phlegm was abundant. In health, the blood was consistent with joy and laughter; but if it in-

creased, man became moody. Yellow bile also denoted health, but when it grew excessive, man became worried. Too much black bile rendered an individual sad and morose, and too much phlegm induced distaste for food.

Stephen Hales, an English clergyman, invented the first instrument for recording blood pressure in 1733. An interval of one hundred and sixty-three years elapsed before a practical and accurate instrument was devised by Riva-Rocci. In 1856, Faivre successfully recorded in man the actual blood pressure. He connected a mercury manometer with the femoral artery and observed the blood pressure to be 120 mm. of mercury. The first practical instrument for blood pressure undertakings was devised by von Basch in 1880. The British Medical Journal in 1880 criticised physicians who depended upon blood pressure instruments for any gainful information. Such information bankrupted a physician's diagnostic acumen.

Long before Jenner successfully introduced his method of smallpox vaccination, the Chinese recognized that fleas of a cow suffering with vaccinia might be used to immunize an individual.

During the Ming Dynasty (1368-1644 A. D.), a materia medica was compiled under the orders of the Emperor by a number of medical men. It recognized a plant known as Mahuang from which our present alkaloid ephedrine is extracted. The pomegranate is also mentioned as a drug. Because of its many seeds, it was symbolic of many offsprings. This fruit was and is now a favorite nuptial offering.

Shen Nung, who ruled China in 2737 B. C., is recognized as the originator of the Chinese materia medica.

During the time of Confucius and for many centuries afterwards, the human body was believed to consist of metal, water, wood, fire and earth. As long as these five elements existed in proper relations, health existed. Any disturbance in these elements was manifested by disease. The five major organs, the heart, liver, lung, spleen, and kidneys, were associated with the five planets, five colors, five tastes, the five climates, and the five elements.

Lazzaro Spallanzani, an unusual anatomist, physicist, and geologist, was born in 1729 and died in 1799. He became a priest at the age of 26 and was appointed professor at the College of Emilia. He soon became interested in spontaneous regeneration, animal reproduction, and artificial fecundation. He made in 1788 his greatest contribution to physiology. He recognized the behavior of the muscular coat of the stomach and of its mucous membrane in the process of digestion. He swallowed the food enclosed in perforated ivory tubes and upon its

MUCILOSE

*Stimulates
Decreases*

**Colonic Emptying
Hypermotility**

The tendency of Mucilose to bring about normal peristalsis solely by bland distention is the mechanism of its clinical effectiveness in spastic colitis and functional constipation.

Mucilose acts by holding water in the feces, preventing dehydration of the bowel content and producing a large, soft and pliable stool which is easily expelled.

Mucilose offers a hemicellulose (vegetable gum) prepared by a special process from the *Plantago loeflingii*. It is available in two forms, both palatable and easy to take—Mucilose Granules and Mucilose Flakes.

removal noted that the food had undergone chemical change. He thus inferred that the muscular coat of the stomach was concerned only in mechanical digestion. He fed sponges tied with threads to different birds and upon their withdrawal, he was convinced that chemical digestion had actually taken place. These experiments were not accepted; no less an authority than John Hunter opposed such conclusions.

The mechanism of parenchymatous respiration was partially described by DaVinci in 1591. He ironically remarked, "All animals perish in an atmosphere in the absence of a burning flame." Spallanzani in 1791

demonstrated gaseous interchange and combustion as a natural phenomenon in all animals. Several Italian physiologists believe Spallanzani discovered the white blood cells in 1768.

Orfila, a pioneer toxicologist, was born in 1787. He was the author of various text books on toxicology. In the year 1817, his first text appeared on medical chemistry; within another year, a second book was presented on the treatment of poisons and asphyxia.

As late as 1775, any applicant seeking an honorary medical degree from St. Andrews University could do so upon the recommendation of two phy-

sicians and the payment of ten guineas.

Ignaz Philip Semmelweiss, born in July, 1818, was graduated in 1844 from the University of Vienna. Puerperal fever at this time was thought to be a form of typhus fever because of its endemic character. The milk theory and suppression of the lochia were also taught as a cause. Semmelweiss became interested in its endemic tendencies, and through an accident, discovered the etiological factor. He had occasion to autopsy a man having died from a generalized septicemia following an infection of a finger. He noted in his post-mortem findings the analogy of septicemia and puerperal fever. Hospital attendants invariably performed autopsies, prepared ligatures in the morgue, and without formality attended women in labor. Semmelweiss concluded that the disease might be carried from the dead to the living. He immediately ordered all attendants to wash their hands in chlorinated lime before attending obstetrical cases. The mortality rate declined. Considerable controversy arose as to the cadaveric theory. At the time he was compiling statistics in support of his conclusion, an outbreak of puerperal fever occurred in his obstetrical ward. He believed a woman admitted to the ward suffering from a discharging wound in the hip to be the endemic source. To his cadaver theory, he then added that living organisms were a most probable source of the fever. This was protested by Pesth, Braun, Hebra the famous dermatologist, Rokitansky a pathologist, Klein, a renowned obstetrician. Both Semmelweiss and his theory were so unpopular that he severed his affiliation as an instructor at the University of Vienna. In 1860, his text appeared on puerperal fever. He performed in Hungary the first ovariotomy in 1863. During this year, he suffered attacks of melancholia, and two years later he was admitted to the insane asylum.

Jean Paul Marat, born in 1743, received an honorary degree at the age of 32 to practice medicine. The requirements for graduation were endorsement by two physicians and the payment of ten guineas (about fifty dollars). Previous to receiving his medical degree, he practised veterinary medicine. At the time or soon afterwards, he published a paper on diseases of the eye and another on gleet. In his community, he enjoyed considerable reputation because of the rapid recovery of a well-known woman who was a patient of his. The drugs he used were carefully guarded. At a later date his secret remedy was found to consist of chalk and water. Apprehensive of a possible revolution, he began the publication of a weekly paper in 1789. His writings were chiefly ironical satires directed toward

The most convenient and
pleasant method of
administering
Gastric Hydrochloric Acid
GLUTAN H-C-L

Indications. The literature shows GLUTAN H-C-L (Glutamic Acid Hydrochloride) to be a superior source of free hydrochloric acid in the treatment of gastric achlorhydria, hypochlorhydria, nervous anorexia, and in secondary anemias requiring a high protein diet, or whenever it is necessary to supplement or replace gastric hydrochloric acid.

Advantages. GLUTAN H-C-L is replacing the old methods of administering hydrochloric acid because—

- No unpleasant taste.
- No sipping through a glass tube.
- No irritation of the esophagus or decalcification of the teeth.
- Put up in capsules which may be carried in purse, handbag or pocket—patients appreciate this convenience factor.
- Contains glutamic acid, a centuries old condiment—acting with hydrochloric acid the two produce a sense of well being after eating that is novel to patients who have long suffered from anorexia due to hypochlorhydria.

Supplied. GLUTAN H-C-L is put up in capsules, each of which is approximately equivalent to 10 minims of diluted hydrochloric acid U.S.P.

Bottles of 100, 500, and 1000 capsules.

The Sippy Diet —

simpler, more effective

with KLIM *Powdered Whole Milk*

COMPARATIVE EFFICIENCY OF CONTROL

FIRST DAY
Percentage control of 46 patients using the first day Sippy Regimen: 54%

Percentage control of 44 patients using the alkalized powdered milk once an hour: 75%

SEVENTH DAY
Percentage control of 14 patients using the routine seventh day Sippy Regimen: 71%

Percentage control of 17 patients using the alkalized powdered milk with six additional feedings: 94.1%

FOURTH WEEK
Percentage control of 14 patients using the routine fourth week Sippy Regimen: 57%

Percentage control of 17 patients using the alkalized powdered milk with three meals: 94.1%

SIMPLER and more effective control of gastric acidity is reported for the following modification of the Sippy Therapy*:

KLIM Powdered Whole Milk 12.5 grams (1½ tablespoonfuls)

Water 90 c. c. (3 ounces)

Add alkali, and feed hourly.

Volume for volume with the standard milk and cream mixture, this KLIM dilution provides 27% more protein for neutralization. Most important, the protein of KLIM forms finer curds, which present a *greater combining surface* to the gastric acid.

Your patients will appreciate the hourly regimen—only 14 instead of 29 medications daily. Patients will tell you, too, that KLIM is more economical, and that it keeps better, because specially packed. Stays fresh for weeks after opening. Available in drugstores everywhere.

Try KLIM in your next ulcer case. Send coupon to receive trial supply and further information on KLIM.

KONSYL

Easily Taken and Well Tolerated

KONSYL, the original concentrated vegetable muciloid made from *Plantago Ovata*, PREVENTS CONSTIPATION.

It is not a laxative in the sense that it will move the bowels

of the person who is constipated, but it will promote normal peristalsis by absorbing water, swelling into a soft, bland bulk and sweeping the fecal contents of the bowel with it.

Konsyl is non-irritating, non-habit forming, easily taken, causes no leakage, and is priced exceptionally low.

Write for clinical test sample and literature.

Also manufacturers of L. A. FORMULA containing Lactose, Dextrin and *Plantago Ovata* Concentrate.

the King and subordinates. He fled to England. Two years later he returned to Paris and lived in seclusion. The following year the King was beheaded, and he then became master of the situation. A young woman opposed to his authority gained entrance to his palace on a false pretense, thrust a knife through his chest, and killed him instantly.

EUSTERMAN, GEORGE B.

Common Gastro-Intestinal Emergencies and Their Medical Aspects. Annals of Internal Med., 12:306-316, Sept., 1938.

A wide variety of diseases and disorders frequently gives rise to disturbances predominantly of gastro-intestinal nature and of sufficient severity to constitute an emergency. Differentiation of an acute abdominal condition that requires prompt surgical interference and a nonsurgical one is the most important function of the physician.

In chronic lesions of the digestive organs the more common complications, perforation, hemorrhage, and obstruction, frequently give rise to conditions which constitute an emergency. Serious disorders engendered by disease remote to the abdominal organs, those of pulmonary, vascular andcretory systems in particular, are chiefly of a gastro-intestinal nature and frequently overshadow the less spectacular but more diagnostic symptoms which are indicative of the organ that is at fault.

Toxemia, variously designated as extrarenal uremia, hypochloremia, azotemia, alkalosis, or nondiabetic acidosis, is a frequent occurrence and constitutes an emergency incident to certain forms of treatment, preoperative stases, or postoperative complications of less frequency and gravity is hypoproteinemia, an important cause of edema and postoperative impairment of gastric motor function. The successful management of these common gastro-intestinal emergencies necessitates their timely recognition and the prompt institution of adequate therapeutic measures.

Hanes M. Fowler, Fort Wayne.

WAKEFIELD, E. C. AND MAYO, CHARLES W.

Functional Sociologic Disorders of the Colon. J. A. M. A., Vol. III, No. 18, Oct. 29, 1938.

This article, with the intriguing and provocative title that it bears, is couched in ideas which are indicative of the new trend in clinical medicine. The recrudescence of an interest by the physician in the social background of functional disease is actually a return to the approach which, in the past, the general practitioner was wont to follow. His knowledge of the

GASTRIC ULCERS

complicated by milk allergy

Gastric ulcers and milk allergy in the same patient preclude the use of ordinary milk.

Fortunately for the patient who has gastric ulcers and who is sensitized to milk at the same time, there is available a form of milk which in addition to being highly suitable for the dietary treatment of ulcers is also free to an unusual degree from allergenic properties.

Pet Milk is, of course, such milk. A sterile whole cows' milk with 90% less curd tension than ordinary milk, it contains whey proteins which, because of their having been coagulated by the heat of sterilization, do not readily escape from the intestinal tract to enter the bloodstream in undigested form. Held in the tract, they are incapable of causing allergic disturbance.

Highly suitable in all cases of milk sensitivity, Irradiated Pet Milk, completely sterile and easy to digest, is particularly adapted to the dietary treatment of gastric ulcers complicated by sensitization to milk.

Samples and literature will be sent on request.

intellectual, moral, religious and genetic background of each of his patients stood him in good stead in diagnosis and treatment.

Drs. Wakefield and Mayo approach the problem of functional disorders of the colon with this same attitude. The use of placebos is positively eliminated from their armamentarium. An appeal to the intellect of the patient is felt to get much better results. They conceive of the problem as arising from a social crisis and being activated by one or more of several factors. These are listed as heredity, congenital faults, environment, irregular habits, food allergy, laxatives, systemic disease, or fear of disease. They make no bones about the matter that although the diagnosis may be arrived at easily, the solution of the problem is far more difficult; for the cause often lies in the defects in our educational system, form of government, religious attitude, morality concepts, and often heredity. The etiologic factors are well discussed, and the presenting symptoms and signs are outlined. The bowel habits can vary from diarrhea to constipation. Typical of the diarrhea is the secretion of large amounts of white stringy mucus. The history is most important in bringing out the vital factor involved. The diagnosis is made by elimination based upon stool studies, sigmoidoscopy, X-ray, gastric analysis for free HCl, and a basal metabolic rate.

The treatment should not include medication, except for the diarrhea, which can be helped to a greater extent by informing the patient as to the etiology of his symptoms. The constipation should be treated with flake or crude agar in cereal or milk.

The cure of functional disorders, they feel, rests upon the adjustment of the individual to his social conflicts. Perhaps it would be much better if the social order could be adjusted to the individual.

Henry H. Lerner.

MIXTER, CHARLES.

The Value of Palliative Surgical Therapy in Advance Carcinoma of the Gastro-Intestinal Tract. *New Eng. Jour. of Med.*, Nov. 10, 1938.

Actuated by an extensive experience and profound sympathetic interest in patients with advanced carcinoma, Dr. Mixter emphasizes the conviction that every possible means to relieve suffering, even at the expense of a high-operative morality, ought to be attempted in such individuals.

The intractable pain of the early, ulcerated lesion or the late metastases are almost unbearable. The development of fistulae following necrosis of the tumor, and the consequent peritonitis or abscesses, he feels should

not be allowed to occur. The vomiting or tenesmus due to mechanical obstruction can all be avoided by radical extensive surgical procedures if necessary.

Multiple resections in several stages should be carried out even though the lesion may be seemingly removable. Metastases, he feels, are not always a contra-indication to resection of the primary growth. Often the results from both the comfort of the patient and the duration of life following such procedures are surprisingly gratifying. The modern colostomy does not in any way incapacitate an individual. The life of lingering wretchedness which is contrasted to one relatively free of suffering in the operated individual is by itself an irrefutable argument for early radical surgical procedure in hitherto so-called advanced inoperable carcinoma.

Henry H. Lerner.

NOBLE, R. L. AND ROBERTSON, J. D.

The Effect of Hypertonic Solutions on Gastric Secretion and Intra-ocular Pressure. *J. Physiol.*, Vol. 4, p. 430, 1938.

Cats under nembutal anaesthesia were used. Gastric secretion was induced by histamine. In so far as gastric secretion is concerned, 30% NaCl (5 cc. per kilo) and 50% glucose (17 cc. per kilo) both caused a dilution of haemoglobin which rapidly returned to normal and inhibited both the acidity and volume of juice secreted. 5% NaCl (5 cc. per kilo) and 50% glucose (5 cc. per kilo), solutions of equal osmotic pressure, caused a similar transitory dilution of haemoglobin but had little or no effect on gastric secretion.

M. H. F. Friedman, Detroit.

SCHIFF, L.

Gastric Secretion in Man. Observations on the Repeated Injections of Histamine and on Transient Achlorhydria. *Arch. Int. Med.*, Vol. 61, p. 774, 1938.

In a trained human subject, repeated (799) subcutaneous injections of histamine over a period of 4½ years were given without harm. There was no overfatigue of the HCl-secreting mechanism. Spontaneous temporary disappearance of free HCl and pepsin occurred.

M. H. F. Friedman, Detroit.

MUSSER, J. H. AND SODEMAN, W. A.

Gastro-Intestinal Expressions of Avitaminosis. *Southern Med. J.*, Vol. 31, p. 397, 1938.

Avitaminoses may give rise to gastro-intestinal symptoms; on the other hand, gastro-intestinal disturbances may result in deficiency expressions. The significance of Vitamins A, B-complex, and C is reviewed.

M. H. F. Friedman, Detroit.

A GAROL HAS HAD A PHYSICAL EXAMINATION

The x-ray says: "Look for uniform density throughout as evidence of soundness"—and Agarol is a thoroughly uniform emulsion that acts the same way with every dose.

The microscope says: "Look for the small uniform oil globules" as a sign of thorough emulsification of Agarol. It means stability, freedom from oiliness, ready miscibility with water, milk, fruit juices or any other liquid.

The pharmacist says: "If it pours freely, it is the sign of a good emulsion." And, indeed, Agarol is a good mineral oil emulsion that has thoroughly proved its value in the relief of acute constipation and in the treatment of habitual constipation.

Ask us for the proof. Descriptive folder and a liberal supply of Agarol is at your disposal, but please write for them on your letterhead.

*Agarol is available in 6, 10 and 16 ounce bottles.
The average adult dose is one tablespoonful.*

PROPOSED REORGANIZATION OF BIOLOGICAL ABSTRACTS

The Board of Trustees of BIOLOGICAL ABSTRACTS, in order to insure the continued solvency of this publication and to extend its usefulness to an increasing circle of scientific workers, has evolved a plan which deserves support from individuals and societies. Briefly, it is proposed to issue the ABSTRACTS in the form of five separate parts, each of which will cover a group of cognate sciences.

I. **GENERAL BIOLOGY**, to include General Biology, Biography-History, Bibliography, Evolution, Cytology, Genetics, Biometry and Ecology. Price \$4.00.

II. **EXPERIMENTAL ANIMAL BIOLOGY**, to include Animal Physiology, Nutrition, Pharmacology, Pathology, Anatomy, Embryology, and Animal Production. Price \$9.00.

III. **MICROBIOLOGY and BIOLOGY**, to include Immunology, Bacteriology, Viruses, Parasitology, Protozoology, and Helminthology. Price \$5.00.

IV. **PLANT SCIENCES**, to include Phytopathology, Plant Physiology, Plant Anatomy, Palaeobotany, Systematic Botany, Agronomy, Horticulture, Forestry, Pharmacognosy, and Pharmaceutical Botany. Price \$6.00.

V. **ANIMAL SCIENCES**, to include Palaeozoology, Parasitology, Protozoology, Helminthology, Systematic Ecology, and Economic Entomology. Price \$6.00.

It is hoped that this partition of the subject matter now covered by the complete edition of the ABSTRACTS, will attract many subscribers to whom the cost of the present publication—\$25.00—would be prohibitive. All subscribers will receive the complete index of the combined volume. Abstracts will appear within two to three months of the time of publication. The editorial policies and standards will be guided by Committees appointed by the representative societies in each field.

Under this new plan, BIOLOGICAL ABSTRACTS may confidently look forward to carrying out the indispensable function of making available to all workers, with promptness and accuracy, the current scientific output in those special and related fields.

Alwin M. Pappenheimer.

1939 MEETING MISSISSIPPI VALLEY MEDICAL SOCIETY AT BURLINGTON, IOWA

The fifth annual meeting of the Mississippi Valley Medical Society will be held in the new \$500,000.00 Municipal Auditorium (to be ready June 1, 1939) at Burlington, Iowa, September 27, 28, 29, 1939. The magnificent new Auditorium at Burlington, only two blocks from the headquarters hotel, will afford the Society the largest and finest meeting place it has ever had. A wonderful Exhibit Hall is being planned which will afford both technical and scientific exhibitors, the largest floor space in the history of the Society.

The Society's officers for 1939 (elected Nov. 20, 1938) are as follows:

President—M. Pinson Neal, M.D., Columbia, Mo. (Elected 1937).

President-Elect—John T. Hanna, M.D., Burlington, Iowa.

1st Vice-President—Joel W. Hardesty, M.D., Hannibal, Mo.

2nd Vice-President—Lindon Sead, M.D., Chicago, Ill.

3rd Vice-President—William M. Hogle, M.D., Keokuk, Iowa.

Secretary-Treasurer—Harold Swanberg, M.D., Quincy, Ill. (Re-Elected).

The following were recently elected to membership on the Board of Directors of the Society:

A. H. Bitter, M.D., Quincy, Ill.; James Graham, M.D., Springfield, Ill.; C. F. Harmon, M.D., Springfield, Ill.; W. L. Hanson, M.D., E. St. Louis, Ill.; C. C. Maher, M.D.,

**ADJUNCTIVE
THERAPY**

Buffer with Kalak

TRADE MARK REG. U.S. PAT. OFF.

AS a valuable aid to sulphanilamide therapy, physicians are prescribing Kalak because

1. It maintains the urine at the desired pH for optimum results (around 7.4).
2. It is ideally suited for inhibiting such untoward symptoms as gastric upset, skin rash, weight loss.

Kalak presents in a palatable, carbonated solution properly balanced proportions of buffer salts which do not increase motility in the intestinal tract. Kalak is not a laxative.

The Kalak formula presents in palatable, carbonated solution

Di-Sodium Phos. Crys. U.S.P.....	309.1 parts per million
Potassium Chloride.....	117.6 parts per million
Sodium Chloride.....	606.0 parts per million
Sodium Bicarbonate.....	5793.0 parts per million
Calcium Bicarbonate.....	770.6 parts per million
Magnesium Bicarbonate.....	101.2 parts per million

Palatable
Sparkling
Neutralizing

Kalak affords a useful adjunct to salicylate, iodide medication, etc.—increases tolerance, enhances the therapeutic effect.

Sultzman, M.D., Hannibal, Mo.; F. G. Ober, M.D., Burlington, Ia.; E. J. Lessenger, M.D., New London, Ia.

FOURTH ANNUAL POST-GRADUATE INSTITUTE

The Philadelphia County Medical Society desires to announce formally, the completion of its scientific program for the Fourth Annual Postgraduate Institute to be held in the Bellevue-Stratford Hotel, Philadelphia, during the week beginning March 13, 1939. The subjects to be considered are those embraced by the terms BLOOD DYSCRASIAS and METABOLIC DISORDERS. These will be further subdivided for convenience in instruction into eighty-six clinical lectures, with open forum discussion for each topic, delivered by as many individual specialists of national distinction.

The pre-eminent position of Philadelphia as a medical center in the past has been justified by its large array of first class hospitals and con-

tributory institutions, and that conservative scholastic atmosphere so essential to careful and dependable research. Despite the development of medical centers in other areas, Philadelphia has continued to maintain its enviable position and it has been the desire of the Philadelphia County Medical Society to release to its own members and to those of the medical profession in general, the results of the labors so diligently conducted within the walls of the city's several medical schools.

The tremendous advances in the medical sciences since the World War have increased the demands of the lay public for medical information. The development of the channels for communication have familiarized the public with medical conditions and terms to such an extent that the physician must keep himself at least informed if not intensely educated concerning the most recent work in the medical field. He cannot conduct his practice along the older lines without continuing his education in the new.

The Postgraduate Institute aims to fill this need and the participants may be assured that they will unquestionably profit by the program to be presented.

THE COMMITTEE.

LEVIN, M.

Morbid Hunger in Relation to Narcolepsy and Epilepsy. J. Nervous Mental Dis., Vol. 88, p. 414, 1938.

Cases of periodic somnolence accompanied by morbid hunger. Periods of days or weeks in which patient eats excessively and shows motor unrest and mental symptoms. Levin suggests that untimely and prolonged inhibition of higher centres results in this hunger and motor unrest. These centres may be those shown by Fulton to exist in frontal lobes, excision of which produced increased appetite and gastro-intestinal hypermotility.

M. H. F. Friedman, Detroit.

MAASSEN, R.

Sekundäre Pellagra nach Gastro-Enterostomie (B₁ — Komplex — Avitaminose). Deutsche Med. Wochenschr., Sept. 23, 1938.

In patient with a gastro-enterostomy there developed a condition typical of pellagra insofar as skin changes and psychic disturbances showed. A diet rich in vitamin B₁ and B₂ was without effect. However, after 6 daily injections of nicotinamide, the skin changes, gastro-intestinal disturbances, and pellagra psychosis disappeared.

M. H. F. Friedman, Detroit.

The Wolf-Schindler Flexible GASTROSCOPE

This instrument presents no risky elements. It is as easily introduced as a stomach pump or rubber tube, thus eliminating danger and discomfort to the patient. It may be turned in any direction and remains flexible during observation. Stomach linings and pylorus appear in natural color with unsurpassed detail within a field of view comprising 50 or 90 degrees. Price \$650. Special tube for local anesthesia \$10. Spare bulbs with rubber finger \$6.50 each, f.o.b. New York.

Studies on Humans with a New Secretagogue Meal

By

ROY UPHAM, M.D., F.A.C.S.*

and

FRANK SPINDLER, A.B., M.D.†

NEW YORK, NEW YORK

WITH the determined conviction that studies of gastric secretions under proper controls would evolve data which would be of value in diagnosis, we have combed the literature thoroughly, and the meal, as evolved by Wilhelmj, appears to be a far step in the approach to the ideal test meal. The results so far reported by Wilhelmj have been confined to studies on dogs and we present this discussion as an attempt at evaluation on human beings.

The more commonly used test meals (shredded wheat biscuits, arrow root cookies, bread or toast, with water or weak tea) are very low in their secretagogue effect thus rendering them inadequate tests of the acid secreting power of the stomach.

"Histamine is a powerful stimulant of the hydrochloric acid secretion yet its action is abnormal in that it stimulates solely the secretion of hydrochloric acid and not that of pepsin and other organic constituents." The alcohol test meal acts as an irritant and its action as a secretagogue is therefore abnormal. Our results with this meal have not been uniformly consistent.

Wilhelmj stated the particular qualifications of the meal as evolved by him are (a) a high secretagogue effect and action through normal channels. (b) Relatively low in organic material and buffer substances thus making for a more accurate titration. (c) No marked change in consistency while in the stomach. (d) Ability to use phenol red as an indicator in order to determine the true composition of the secretions entering the stomach. (e) Liquid consistency so that phenol red is not absorbed by solid particles. (f) The test meal should have no acid neutralizing or combining power and finally (g) it must be possible to standardize the test meal before use. The meal was made up in a two per cent solution as follows:

1. 40 grams of Liebig's extract (Lemco Brand) are dissolved in one liter of distilled water.
2. Add 30 mgm. of the sodium salt of phenol red dissolved in 33 cc. of 1/10 N NaOH.
3. Add 20 cc. of a 20% solution of sodium carbonate. The solution is now alkaline.
4. Add slowly with constant stirring one liter of 1/10 N hydrochloric acid. The solution is now acid to litmus paper.
5. Allow to stand until a heavy flocculent precipitate settles out.
6. Filter until crystal clear.

This gave us two liters which was ample for use in six tests. The meal should have a titration value of between 11-22 cc. of 1/10 N acid. If it runs higher than these figures more alkali may be added to bring it within these limits.

In the course of experimentation we found that better colorimetric readings were obtained by using

twice the amount of phenol red and sodium hydroxide suggested in the preparation of the test meal.

"By preparing such a solution all undesirable material was removed by the acid added, and secondly, sufficient base was supplied to care for the non volatile acids. Thirdly, by leaving the solution slightly acid with hydrochloric acid, its acid neutralizing and combining powers would be saturated." To adapt the test for clinical use in the physicians office, it was found practical and time saving to prepare several liters of the meal at one time. The preparation of a single meal requires at least two hours time, but multiple quantities can be elaborated in the same period. The preparation of the meal requires a person adequately trained in chemical procedures. It may be stated that the extraction is no more time consuming than that of an ordinary fractional meal. Subsequent chemical procedures and the added mathematical computations involved are so time consuming that it appears the meal, in its present form, is not applicable as ordinary office procedure, but must be classed more as a research implement.

Reviewing some of the complexities and difficulties arising in experimentation we found, that in order to handle a large group of cases, it was necessary to have available a properly equipped laboratory both as to space required and equipment needed.

The taste, appearance and ease of administration through tube trained patients and the use of the meal by mouth is so acceptable that all elements of psychic depression of the gastric physiology were reduced to a minimum. Varying our technique somewhat from that suggested by Wilhelmj, our meals (in a designated number of cases) were prepared with acid values which ranged from 9 cc. of 1/10 normal hydrochloric acid per 100 cc. to 30 cc. of 1/10 normal acid.

The amount of meal administered varied from 150 cc. to 500 cc. In each case, however, specimens were removed every half hour until the stomach emptied. The meal was administered to a large series of gastrointestinal cases previously studied and an attempt was made to secure controls by its use on normal human beings. The latter group consisted of medical students who volunteered their services. In the entire series of cases a fractional study (arrow root crackers and water or the alcohol-phenolsulphonphthalein test meal) was available for comparison. The number of patients we could reasonably handle at one time did not exceed twelve in number with two trained technicians in charge, and the mathematical computations required the remaining time of a working day.

Experimentation with the quantity of test meal fed to patients revealed the fact that smaller amounts, in contrast to the work done on dogs, gave the greater number of half hourly yields. There were a few ex-

*Associate Professor of Medicine at New York Medical College Head of the Section of Gastro-Enterology and Attending Gastro-Enterologist at Flower Fifth Avenue Hospital and Metropolitan Hospital.
†Clinical Assistant in Medicine-Gastro-Enterology, Flower Fifth Avenue Hospital and Metropolitan Hospital.
Submitted April 21, 1933.

ceptions to this. At first 500 cc. of the meal was used as a standard for both male and female patients. Our results in so far as the number of half hourly specimens obtained were low; especially in the group with gastric pathology. As would be expected with post-pyloric lesions, and angulation of the duodenum due to visceroptosis, a greater number of yields was obtained regardless of the amount of meal administered. In the remaining cases, the meal being liquid, was found to empty fairly rapidly. After a series of tests 300 cc. portions were found to give the greatest number of return specimens taken every half hour. Patients with a previously diagnosed achylia gastrica, emptied the stomach rapidly regardless of whether 300, 500, or 600 cc. was administered to them. In most of the terminal gastric catarrh cases the use of 300 cc. gave us at least three specimens. In comparing our work with that done by Mr. James Wills at the Medical College of Virginia several years ago on a meat extract preparation, it was interesting to note the similarity of results in many respects. He states, "that the response to meat juice is somewhat more rapid than that to the Ewald test meal. Also the fall is somewhat sharper. It is worth note in this latter consideration that with meat juice the emptying time of the stomach is about an hour and three-quarters, while with the Ewald test meal the emptying time is two and a half hours."

Attempts were then made to determine any changes in acidity when the patients took the meal by mouth or tube. Each patient had at least three extractions performed at different times. The manner in which this was done was to introduce the meal via the tube the first two investigations, and lastly the patient was allowed to drink the meal and the tube was passed in fifteen minutes. The changes in titration of acidity in the yields were not marked. In fact, the type of curve of each investigation was so similar as to render the differences negligible in our estimation.

Fig. 1 (a)

Fig. 1 (b)

Only one untoward reaction was evidenced by a woman who stated that she became extremely nauseous and vomited after returning home. This patient, it was noticed, ran a great amount of bile in each specimen from the first yield on. The fact that she had a posterior gastro-enterostomy performed some time previous to the experiments throws some light on that situation.

There are five types of normal curves described by Wilhelms in his work on the intact normal stomach of dogs and the whole stomach isolated from the intestine.

Type I comprises about half the total number, types II and III about 30%. Curves of type IV and V are due to lessened duodenal regurgitation and absorption of non acid fluid from the gastric contents.

The majority of so called normal cases in our series follow a curve as illustrated:

Fig. 2

Here we notice a sharp rise in the acid secretion during the early part of the experiment and a fairly sharp fall in the acid curve, during the latter part. This is in concurrence with the findings of Wills as quoted previously in this paper. The result is obvious when we consider that of all the test meals evolved, the meat extract or so called secretagogue meal acts to a greater extent as a physiological stimulus than any of the other procedures. Therefore, we have accepted the above charted curve as the predominant normal curve, and based our succeeding findings on it. The exceptions to this were found in the following:

Group I—Duodenal ulcer with pyloric obstruction.

Here we see a very sharp rise in acid in the first

Fig. 3

hour with a very gradual tapering off in the acid curve and a greater number of specimens. In fact only limitation of time prevented further withdrawal of half hour specimens beyond the third hour. The acid fluid in the early yields composed the greater part of the total fluid in the stomach, but as we drew toward the second and third hour yields, there was a greater addition of non acid secretion to the gastric contents. Apparently there was some reabsorption of water by the stomach wall but this is not marked. Duodenal regurgitation also played a part as a neutralizing factor in the latter part of the experiment.

Group II—Duodenal ulcer without obstruction.

In this group there is again a very sharp rise in the

Duodenal Ulcer Without Obstruction

Fig. 4

acid curve in the first hour and almost as sharp a drop in the second hour. The acid fluid remained fairly high throughout the yields. As a rule we were unable to obtain more than four specimens in similar cases. The secretions pouring into the stomach cavity however, remained fairly high in acid composition.

Group III—Sub-Acid Gastric Catarrh (slight acid production).

The curve is low and plateau type. The amount of

Fig. 5

non acid fluid is greatly out of proportion to the acid fluid. The secretions poured forth by the stomach wall are in the main non acid. As a general rule its acid content is so low that frequently it dilutes the acid content of the test meal. In many of these cases the alcohol and the Ewald meal called forth no acid production at all, again illustrating the more apparent stimulatory effect of the secretagogue meal.

Group IV—Total acidity. In this group there was no acid production. In fact the acid in the test meal was neutralized by the gastric and extra-gastric secretions in all specimens.

Cholecystitis and cholelithiasis cases gave us no curve of diagnostic value at present. It may be stated that as a general rule gall bladder disease produced lower acid curve than normally found. Possibly in a larger series of cases there may be more definite conclusions arrived at.

Let us briefly compare some of the results obtained with the alcohol-phenolsulphonphthalein, cracker and water and the secretagogue meals. It was found that the alcohol test often developed no acid whereas the secretagogue and arrow root cracker meals did in the same patient. The stomach definitely reacted to the beef extract preparations, which was found to be more stimulating to acid production than carbohydrates. In some cases the secretagogue meal produced some acid even where histamine had failed. This was particularly observed in cases of terminal gastric catarrh where no acid was produced in any specimen by the use of histamine. In such cases the use of the secretagogue meal frequently called forth acid production in the second hour even though there may have been an anacidity in the first hour yields.

A further observation was made in comparing the secretagogue meal with the arrow root cracker meal. Here it was seen that the former called forth an early secretion of acid by the stomach which dropped consistently from the second hour specimen. On the other hand a direct reversal of this curve was seen with the cracker meal. Here the curves recorded a later elevation of acid. It would seem therefore that the secretagogue meal has the power of stimulating the stomach to immediate activity, and as there is no substance in the meal to bind the hydrochloric acid produced, exact figures for gastric acidity can be computed. The secretagogue meal is ideal in that it gives a true picture of the acid curve produced by the stomach, whereas, with the ordinary Ewald cracker meal, there is a binding of the hydrochloric acid by the meal in the first hour which confuses and makes unreliable the acid values. The secretagogue meal gives exact knowledge of the time of production and volume of acid produced in the stomach and a definite rate that it is neutralized by a non acid secretion. We are able to determine the relation of the acid to the non acid secretion and we are further able to evaluate the amount of non acid secretion produced by the stomach in comparison with the amount of regurgitated material from the duodenum. In subsequent papers we hope to evaluate the curves of true gastric ulcer, and to reveal the position of the so called neuroses in relation to gastric pathology.

The Bete Noir of gastric diagnosis has been the large group of cases which have been classed as functional neuroses.

The authors feel that the fact can be established that with the earliest trauma of the nervous system and psychic instability there is a variance in the nerve balance of the stomach, and with that there are quantitative and qualitative changes in the acid and the non acid secretion of the stomach which up to this time have defied evaluation.

It would appear that the secretagogue meal would detect these changes in gastric secretion and a large group of cases which, while they may have their origin in nervous imbalance, will be shown to have disturbance of gastric function which can be based upon abnormal physiology.

In future experimentation attempts will be made to

alter the meal considerably by increasing the per cent of the solution prepared. We have already increased the amount of phenol red over the quantity suggested by Wilhelmj with clearer and more consistent results.

METHODS OF ANALYSIS

The analysis consists of two procedures: (1) titration of a sample of the test meal and of the samples removed from the stomach. (2) determination of the per cent of phenol red in the samples removed from the stomach.

The procedures as outlined by Wilhelmj are briefly:

1. Titration of the test meal and of the gastric samples.

5 cc. of a centrifuged sample of gastric contents or an uncentrifuged sample of the original meal is diluted with 75 cc. of distilled water and placed on a water bath for 30 minutes. Six drops of brom cresol purple are added and the titration is performed using 1/20 N NaOH. The result is expressed as cc. 1/10 N acid per 100 cc. of gastric sample or test meal. The end point is a rich wine colored purple. The titration value obtained is for total acid.

2. Determination of the per cent of phenol red in the gastric samples

5 cc. samples of the original test meal and of each of the gastric samples are placed in 15 cc. centrifuge tubes. Add 2 cc. of 20% sodium tungstate. Then add 2 cc. of 1.33 normal sulphuric acid and mix by inverting the tubes. Stopper the tubes. Allow to stand 1 to 1½ hours until a precipitate settles out. Centrifuge at high speed for 10 minutes. Decant the supernatant fluid into graduated centrifuge tubes. Reduce the volume to 8 cc. Add 1 cc. of 20% NaOH mix and centrifuge again. Compare the gastric samples with the sample of the original test meal in a colorimeter and determine the per cent of phenol red present. Set the standard at 5 mm. and make the comparison on this basis.

Bile tinged gastric samples may be matched by adding a small amount of picric acid to the standard.

For very diluted gastric samples, equal parts of the original test meal may be added and correction in calculation made as follows: The per cent of phenol red in the diluted sample minus 50 times 2 equals the per cent of phenol red in the original undiluted sample.

Bile, in the gastric sample may be tested by a Pottenger ring test.

In the calculations we must determine: (a) The acid in the test meal corrected for dilution. (b) The extra acid. (c) The acid concentration of the gastric secretions. (d) The per cent of phenol red. (e) The total fluid. (f) The acid fluid. (g) The non acid fluid. (h) The per cent of acid fluid.

We determine (a) by multiplying the cc. of tenth normal acid in the original test meal by the per cent of phenol red in the gastric sample. The result is subtracted from the acidity of the gastric sample to give us (b). The acid concentration of the gastric secretions (c) is derived by dividing the extra acid by the decrease in the per cent of phenol red (100% phenol red) and multiplying by 100. The total fluid (e) is shown by the decrease in the per cent of phenol red (100% phenol red). The acid fluid (f) is derived by dividing the extra acid by 1.7 (Hollander, F. "Studies in gastric secretion; Composition of gastric juice as a function of its acidity"). The non acid fluid represents the difference between the total fluid and the acid fluid. It consists of mucus and mucoid secretions of the pyloric and fundic areas, fluid of secreted acid which was neutralized and regurgitated duodenal secretions.

EXAMPLE

Test meal—20 cc. 1/10 normal acid per 100 cc. Gastric samples:

30 minutes	— 40
60 minutes	— 50
90 minutes	— 50
120 minutes	— 52

Per cent of phenol red:

30 minutes	— 85%
60 minutes	— 65%
90 minutes	— 50%
120 minutes	— 25%

1. To determine the acid in the test meal corrected for dilution—multiply the cc. of 1/10 normal acid in the test meal by the per cent of phenol red.

20 x 40 equals	8 cc.
20 x 50 equals	10 cc.
20 x 50 equals	10 cc.
20 x 52 equals	10 cc.

2. To determine the extra acid—subtract the acid in the test meal corrected for dilution from the acid in each gastric sample.

40 — 8 equals	32
50 — 10 equals	40
50 — 10 equals	40
52 — 10 equals	42

3. To determine the acid concentration of the gastric secretion—divide the difference in the per cent of phenol red (100% PSP) into the extra acid and multiply by 100.

32 ÷ (100-85) x 100 equals	214
40 ÷ (100-65) x 100 equals	114
40 ÷ (100-50) x 100 equals	60
42 ÷ (100-25) x 100 equals	56

4. To determine the total fluid—subtract the per cent of phenol red from 100.

100 — 85 equals	15
100 — 65 equals	35
100 — 50 equals	50
100 — 25 equals	75

5. To determine the acid fluid—divide the extra acid by the constant 1.7 and multiply by 100.

32 ÷ 1.7 x 100 equals	10
40 ÷ 1.7 x 100 equals	24
40 ÷ 1.7 x 100 equals	24
42 ÷ 1.7 x 100 equals	25

The non acid fluid is the difference of the acid fluid subtracted from the total fluid.

SUMMARY AND CONCLUSIONS

1. The meat extract meal is a more exact and constant meal than any previously reported.

2. The test does not lend itself readily for use by the average practitioner. It is more the character of a laboratory procedure, and adequate facilities are necessary for its use, together with the assistance of trained technicians.

3. It gives a great deal more information than any other procedure as to the actual amount of HCl produced by the stomach and the time it is evolved as well as the amount of non acid and acid fluid added to the gastric contents by the stomach wall and duodenal regurgitations.

4. The secretagogue meal gives absolute figures as to the amount of hydrochloric acid produced by the stomach and eliminates the error produced by other meals which have ability to combine with the hydrochloric acid and produce false values.

5. A larger series of cases will be attempted before further definite conclusions are arrived at.

Peptic Ulcer of the Esophagus

By

DONALD T. CHAMBERLIN, M.D.*
BOSTON, MASSACHUSETTS

THIS study was made in an effort to clarify the diagnosis of peptic ulcer of the esophagus, to offer certain diagnostic criteria which must be fulfilled before the diagnosis can be established, and to point out an etiologic factor which previously has been overlooked. The literature is chaotic—many cases have been reported without adequate verification; some authors have based their diagnosis only on the presence of an ulceration of the esophageal mucosa without inflammatory signs; others on the presence of a high free acidity and periodic epigastric pain or substernal distress.

The disease is characterized by dysphagia, subxiphoid distress occurring one to two hours after meals and relieved by food or soda, hemorrhage and occasionally, perforation. It differs from peptic ulcer elsewhere in that certain definite conditions which are known must be present before it can occur. Aurelius (1), Hurst (8), Friedenwald (5) and Stewart (17) have all pointed out that the two conditions necessary for the production of peptic ulcer of the esophagus are the presence of heterotopic gastric mucosa in the esophagus, or a patent cardia through which gastric juice is constantly regurgitated into the esophagus. Both of these conditions may exist together, but one or the other must be present. None of these authors suggests any abnormality which might cause this patency of the cardia. This we propose to do later in this discussion. Stewart and Hartfall (17) found a marked association with diseases in which vomiting is a prominent feature, and in association with gastric and duodenal ulcer. However, they suggest that aberrant gastric mucosa must be present. Friedenwald and his coworkers (5), in 1928, were able to produce experimental chronic ulcers in the esophagus of dogs by traumatizing the esophageal mucosa and then bathing the traumatic ulcer with 10 per cent hydrochloric acid. They found that the esophageal mucosa rapidly healed if the hydrochloric acid was withheld.

The first case report of this condition was by Albert in 1839. The histologic pathology was first reported by Quinke in 1879. In 1926, Von Hacker and Lothiesieu collected ninety-one cases, but very few were verified by autopsy. In 1929, Friedenwald and his coworkers (6) gave an excellent summary of the literature and reported thirteen cases from their own practice, all verified by roentgenologic examination and esophagoscopy. In the available literature of the past ten years, excluding Friedenwald's thirteen cases, there are thirty, all verified either by biopsy through the esophagoscope or at autopsy. There are several other cases which are called peptic ulcer, but are either acute, associated with diabetes or tuberculosis or are in some other way of doubtful origin and cannot be considered as true peptic ulcer of the esophagus.

Chevalier Jackson (10) reported eighty-eight cases in 1929, twenty-one active and sixty-seven healed, found in 4,000 consecutive cases in which esophagoscopy was performed for disease of the esophagus, and could find no evidence of increased patency at the cardia, but he made no report of the roentgenologic findings.

Hunt and Stewart collected eleven cases in 1934, and reported three of their own. Stewart and Hartfall (17) found one case in 10,000 consecutive autopsies and gave as the incidence, 0.6 per cent of all autopsies, in a review of the literature. E. Sköld (16) stated that the occurrence is 0.03 to 0.16 per cent of all lesions of the esophagus.

Because of the confusion existing in the literature over the diagnosis of peptic ulcer of the esophagus, we offer the following diagnostic criteria:

1. The ulcer must be unassociated with systemic disease. This condition is made because of the tendency to call any ulceration of the esophagus a "peptic" ulcer, even in the presence of diabetes and tuberculosis. We do not imply that systemic disease renders one immune to peptic ulcer, but that in the presence of certain diseases an ulcerated mucous membrane

*Department of Gastro-Enterology, The Lahey Clinic.
Submitted May 23, 1935.

is more likely to be a result of the disease than a separate entity.

2. The ulcer must be seen at esophagoscopy or at autopsy.

3. Free gastric hydrochloric acid must be present.

4. The ulcer must be chronic.

5. The symptoms must be relieved by peptic ulcer therapy and dilatation.

In the discussion of etiology, many authors (Hurst, Stewart, Friedenwald, Aurelius) mentioned the presence of aberrant gastric mucosa in the lower third of the esophagus, where all these lesions occur, and the regurgitation of gastric hydrochloric acid through a patent cardia. None, however, suggested why the cardia is patent. In only one case, that of a child of three with a congenital, short esophagus, was the length of the esophagus or the presence or absence of diaphragmatic hernia mentioned in the literature of the past ten years. There have been seven patients with peptic ulcer of the esophagus in The Lahey Clinic in the past ten years, verified by esophagoscopy and satisfying the requirements mentioned above. Of these, six had either short esophagus, diaphragmatic hernia or both. The other patient had aberrant gastric mucosa in the lower third of the esophagus. We believe this to be of great significance. It is obvious that wherever there is gastric mucosa there is always the potentiality of peptic ulcer, and it was shown by Friedenwald that a constant bath of hydrochloric acid will produce an ulcer in the absence of aberrant gastric mucosa. The two essential factors, then, for the production of peptic ulcer of the esophagus need not be present simultaneously, but one or the other must be, and it is our belief that short esophagus and diaphragmatic hernia have been overlooked in the cases reported heretofore, and are a definite factor in the production of peptic ulcer of the esophagus.

Roesler (15) suggested that cardiospasm, as such,

TABLE I
Age and sex incidence (from the literature)

Years	Male	Female
0-10		1
11-20		
21-30	2	
31-40	3	1
41-50	6	2
51-60	4	3
61-70	1	
71-80	2	
Totals	17	7

may play a part in the etiology of peptic ulcer of the esophagus, but it is more likely that cardiospasm is an effect rather than a cause, and is brought about through the inflammatory reaction around the ulcer. We have reviewed sixty cases of cardiospasm, uncomplicated by other gastro-intestinal conditions, in all of which esophagoscopy was performed. These patients were seen in the clinic during the past five years. In none of them has a peptic ulcer been detected subsequent to treatment.

A striking characteristic of the disease is its most

frequent occurrence during the fourth and fifth decades. The age and sex incidence of the cases reported in the literature are given in the table. In six case reports, the age and sex were not given.

In Friedenwald's series of thirteen (included in the table) the sex incidence was more evenly divided, six males and seven females. In our short series of seven, there were three males and four females; one, fifty-six years; two, sixty years; two, sixty-six years and two, seventy-five years of age.

In our series, roentgenologic examination revealed diaphragmatic hernia and short esophagus together in four cases; diaphragmatic hernia alone in one and short esophagus alone in one. In the seventh case neither of these abnormalities was found but subsequent autopsy revealed heterotopic gastric mucosa. Five of our seven patients gave a history of typical ulcer pain associated in the later stages with dysphagia and regurgitation of undigested food. One patient gave a history of dysphagia only. The other

Fig. 2 — Case 1

patient had only the symptoms of cardiospasm; in this case, the first gastric analysis showed no free acid. This is a frequent finding in cardiospasm, and was probably due to inability to pass the tube into the stomach. Later, free acid was found in this case also.

All seven patients did well on Sippy management without local treatment except dilatation except one who required phrenicectomy before relief was obtained. Esophagoscopy a month later revealed healing and the patient remained free from symptoms. There are many cases in the literature in which local applications of 10 per cent silver nitrate solution directly to the ulcer were of great benefit in ameliorating pain and hastening healing, though most authors reported

Fig. 3—Case 2

the use of alkali therapy in conjunction with the local treatment.

Many small, asymptomatic diaphragmatic hernias are seen in the course of a gastro-enterological practice, and occasionally a patient with pain, vomiting or hemorrhage in whom only a diaphragmatic hernia is demonstrable by the roentgenogram. Usually these patients do well on ulcer management and the diagnosis is left at diaphragmatic hernia. Wilkinson (18) (1934) reported a study of seventy patients with diaphragmatic hernia, of whom forty had symptoms suggestive of peptic ulcer, yet of these, esophageal ulcer was found in three cases and gastric or duodenal ulcer in seven. There is no mention made of esophagoscopy in these forty patients. It is our belief that if esophagoscopy were done in these patients, peptic ulcer would be found in more of them, and further that peptic ulcer of the esophagus is not as rare a condition as the reports in the literature lead one to believe. Wilkinson also found the majority of his patients had a short esophagus and stated that "it seems probable that most of these are of congenital origin, but it is unlikely that the defect has always been present. If this were true, more hernias should be discovered in younger individuals, whereas the average age is fifty-four." It is unlikely that a short esophagus is a complication of peptic ulcer of the esophagus caused by the inflammatory reaction and scar tissue formation, since in the majority of cases it is present with diaphragmatic hernia as a predisposing factor.

Our seven cases are reported briefly below.

CASE REPORTS

Case 1. A woman, aged sixty, was admitted to the clinic on February 7, 1932. For three months previous to her

admission, she had had dysphagia on attempting to swallow solid food and, for three weeks previous to admission, some subxiphoid pain about an hour after meals, relieved by taking soda or food. Liquids caused no symptoms.

Physical examination revealed evidence of cerebral sclerosis; otherwise her examination was negative. On laboratory examination a hypochromic anemia was found. Gastric analysis showed 36 per cent free hydrochloric acid. On roentgenologic examination after a barium meal, a short esophagus was revealed, with a diaphragmatic hernia involving about a sixth of the stomach (Fig. 1). In the esophagus just above the hernia an ulcer niche was seen. Esophagoscopy revealed scar tissue, about an inch in length, involving the entire lower surface of the esophagus, in the center of which, on the posterior wall, was an ulcerated area about 0.5 by 1.5 cm. The patient was placed on ulcer management with immediate relief of pain, and was given an occasional dilatation. On roentgenologic examination a year later no ulcer niche was seen, although the short esophagus and diaphragmatic hernia were still present. Her blood count was normal. At this time the patient was working.

Case 2. A woman, aged sixty-six, entered the clinic on July 7, 1933, because of hematemesis and dysphagia. Five years previous to admission she was seized with a severe pain in the interscapular region, which lasted three to four weeks and was followed by another hemorrhage. For six months previous to her admission she had suffered

Fig. 4—Case 3

from occasional regurgitation of undigested food when she was nervous or upset.

Physical examination revealed that the patient was obese with marked arteriosclerosis, but no other abnormal findings. Erythrocytes numbered 4,750,000. The value for the hemoglobin was 80 per cent. Gastric analysis revealed the free hydrochloric acid to be 21. On roentgenologic examination after a barium meal a short esophagus was found with a diaphragmatic hernia involving about one-

Fig. 5—Case 4

eighth of the stomach above the diaphragm (Fig. 2). On esophagoscopy, a short, dilated esophagus was seen and, at the junction of the esophagus with the stomach, a superficial ulceration, 2 by 1 cm., was made out. At biopsy, chronic inflammation was found. The patient was placed on ulcer management and did well for one year. She then had a hemorrhage and died in December, 1934.

Case 3. A man, aged seventy-five, entered the clinic on June 26, 1930, with a chief complaint of dysphagia of two and a half years' duration. For the past two and a half years he had been unable to eat anything but soft foods because solids caused substernal pressure which was almost unbearable for one to four hours following ingestion. He occasionally regurgitated mouthfuls of undigested food.

Physical examination revealed that the patient was undernourished, with limited diaphragmatic excursion and some emphysema, but no other abnormality. Erythrocytes numbered 3,780,000; the value for the hemoglobin was 60 per cent. Gastric analysis revealed free hydrochloric acid of 80. On roentgenologic examination after a barium meal a diaphragmatic hernia was found above which the esophagus was narrowed for about a third of its length (Fig. 3). Esophagoscopy revealed a narrow fibrous stricture above the junction of the stomach with the esophagus, with a bleeding area on the posterior wall. This patient was placed on ulcer management with relief of symptoms and, with occasional dilatation, did well.

Case 4. A woman, aged sixty-six, was admitted to the clinic on February 1, 1937, with a chief complaint of regurgitation of food of fifteen months' duration. For the past fifteen months this patient had had frequent attacks of subxiphoid pain of a griping nature, accompanied by regurgitation of undigested food, without nausea or retching. After she regurgitated, the spasm disappeared and she could return and eat.

Physical examination was essentially negative. On laboratory examination, the erythrocytes numbered 4,100,-

000 and the value for the hemoglobin was 76 per cent. Free acid on her first examination was negative. Gastric analysis done at the time of esophagoscopy revealed the free hydrochloric acid to be 35. On roentgenologic examination after a barium meal a short esophagus, considerable cardiospasm and irregular dilatation of the lower end of the esophagus were found (Fig. 4). On esophagoscopy, a short esophagus was seen. There was an ulcer on the right side at the lower end of the esophagus, with scarring and narrowing of this portion. At biopsy, aberrant gastric mucosa was found. She was placed on ulcer management with occasional dilatation and did very well.

Case 5. A man, aged fifty-six, entered the clinic on January 15, 1935, with a chief complaint of indigestion of eight years' duration. For the past eight years he had had typical ulcer symptoms, consisting of epigastric pain coming on an hour to an hour and a half following meals, relieved by food or soda, and occasionally awakening him at night. In December, 1932, he had had a severe gastric hemorrhage after which he had been in bed for one week. In April, 1933, he again had vomited blood and this time was placed on a Sippy regime. He had recurrence of pain in 1934. At no time was an ulcer demonstrated. In August, 1934, he began to vomit a few mouthfuls of food occasionally after which he could eat a full meal undisturbed.

Physical examination gave essentially negative results. On laboratory examination the erythrocytes numbered 5,340,000; the value for the hemoglobin was 95 per cent. Gastric analysis showed the free hydrochloric acid to be 23. Roentgenologic examination revealed an irregular constriction of the lower third of the esophagus (Fig. 5). Esophagoscopy showed a short esophagus with an ulceration (2 inches) on the left anterior wall at the junction of the stomach with the diaphragm. Two inches of the stomach were above the diaphragm. This patient was placed on ulcer management and dilatation was performed, but without relief. Finally a phrenicectomy was done after

Fig. 6—Case 5

Fig. 7—Case 6

which beginning healing was found on esophagoscopy done a month later. Ulcer management was continued. A roentgenogram on October 14, 1935, revealed a smooth constriction without any hesitation in the passage of the meal. On his last visit to the clinic, October 31, 1936, he had no complaints.

Case 6. A man, aged seventy-five, was admitted to the clinic on March 25, 1932, with a chief complaint of intermittent dysphagia of two years' duration. For two years previous to his admission he had had a pressure sensation in his epigastrium, coming on when he sat down to eat. Until considerable mucus had been regurgitated he had epigastric distress and could not get any water into his stomach. He had never had night distress or typical ulcer symptoms.

Physical examination revealed a mild parkinsonism, bilateral inguinal hernia and, except for the evidence of arteriosclerosis, gave otherwise negative results. On laboratory examination the blood and urine were normal. Gastric analysis revealed the free hydrochloric acid to be 20. Roentgenologic examination of the esophagus showed a dilatation of the upper three-fourths of the length, and a narrowing for 2 inches above the cardia (Fig. 6). On esophagoscopy, a narrowed firm stricture was found, resembling scar tissue, at the lower end of the esophagus. The mucosa below this was gastric. There was a small granulation on the anterior aspect of the stricture. At biopsy, aberrant gastric mucosa was found. He was given a bland diet, alkaline powders three times a day and, when necessary, dilatations were performed at frequent intervals for two years. On his last visit to the clinic, July 14, 1934, he had no difficulty whatsoever.

Fig. 8—Case 7

Case 7. A woman, aged sixty, was admitted to the clinic on January 10, 1938, with a chief complaint of difficulty in swallowing of two years' duration. For two years previous to her admission, the patient complained of a sense of obstruction in the esophagus whenever she swallowed her food. A bolus would produce choking and regurgitation of food. At first it occurred at every meal; later it was found that by eating slowly and taking soft foods she experienced no difficulty. She had no indigestion nor associated pain, and only occasional belching.

Physical examination gave essentially negative results. The erythrocytes numbered 4,360,000; the value for the hemoglobin was 85 per cent. Gastric analysis showed a free hydrochloric acid of 36. Roentgenologic examination of the esophagus showed it to be normal down to a point 1 inches above the diaphragm. From this point to the diaphragm the esophagus was narrowed and had an irregular outline. The films suggested a small, penetrating lesion was present. The stomach was normal (Fig. 7). On esophagoscopy, a narrowing of the esophagus was found 2 inches above the cardia. There was no evidence of a fresh ulcer but it was felt that the stricture was due to an old ulcer. The patient was given a bland diet and dilatation was performed twice. To date she has been free from symptoms.

SUMMARY

1. An etiologic factor in the production of peptic ulcer of the esophagus, previously overlooked, is noted.
2. Certain diagnostic criteria are suggested.
3. Seven cases are reported.

Food Allergy and its Rationalization*

By

H. C. BRADLEY

and

S. BELFER

MADISON, WISCONSIN

RECENT papers in this Journal and elsewhere (1, 2, 3, 4) have advocated the therapeutic use of pancreatic enzyme preparations for food allergies. By way of rationalization, an entirely new physiology of digestion has also been proposed.

It is not our purpose to question the clinical observations. The final appraisal of any therapeutic measure must be made by clinicians and will depend wholly on clinical observation. The suggestion that certain allergic cases clear up as their digestive deficiencies are improved is not a new one (5), and has never been in conflict with well-established physiological data. We believe the fallacies involved in the proposed new theory of digestion should not go unchallenged.

Briefly stated, the papers of Oelgoetz *et al* assert that the major functions of digestion are carried on in the blood stream. "The gastro-intestinal tract is essentially a receiving, mixing and eliminating organ." In it the food materials combine with amylase, lipase, and trypsin, and in this form are absorbed, along with any excess of free enzymes. The food materials are then digested in the blood to harmless end-products. When pancreatic secretion is deficient, there is subnormal enzyme concentration in the blood stream and digestion there is delayed. Tissue cells are thus exposed to toxic intermediate protein fragments, and the symptoms of allergy develop. Excess enzymes are not found in the blood, but are stored in the tissue cells—which are unable to provide their own. Enzyme concentration in the tissues is exactly one hundred times that of blood. Brain and heart, however, are said to have no enzymes. In blood, lipase, amylase, and trypsin are present at a fixed level and in parallel concentrations, so that measuring one of them is equivalent to measuring all. In allergies, the blood enzyme level is low because of inadequate pancreatic secretion, and this may be corrected by feeding active pancreatic preparations. A test is recommended for determining the functional adequacy of the pancreas, which depends upon the decolorization of starch iodide by serum, and is said to be a test for amylase. Evidence

is claimed for the automatic control of pancreatic secretion by the enzyme level in the blood.

In the following paragraphs we propose to examine critically some of the more striking assertions advanced by Oelgoetz and the evidence upon which they rest.

What is the evidence for massive absorption of undigested foods as a preliminary to digestion in the blood? There is none. Walzer's work is referred to (6) as authority for such a conclusion. What it actually proved, however, was that normal persons as well as allergic ones frequently show traces of absorbed food proteins in the blood. The success of Walzer's experiment depended on the most delicate test yet devised for protein, and objectively demonstrated in the normal person, what the allergic symptoms had long made clear in the highly sensitive individual. The primary fallacy here is the assumption that a minute trace of food antigen absorbed, proves that the entire meal is thus absorbed. Oelgoetz states specifically that alkali albuminate is absorbed and is present in the blood stream. But it has never been found there by Oelgoetz or anyone else.

Verzár's work (7) indicates that undigested fats are not absorbed.

Starch is easily detected by a delicate color reaction, and if absorbed as such would constitute evidence in favor of Oelgoetz's assumption. It has never been found in the blood.

There evidently is no factual basis for the assumption of extensive food absorption.

What evidence for digestion taking place in the blood stream? The presence of the enzymes lipase, amylase, and proteinase.

What evidence that these are derived from pancreatic juice? Their specific origin has not been well established. They may indeed come from the pancreas either directly, or by absorption of pancreatic juice. The recent work of Crandall, Comfort and Osterberg (8, 9, 10) relates high serum lipase with pancreatic pathology. The enzymes may also be derived from leucocytes.

Of what significance are these enzymes? In Oelgoetz's hypothesis, the only enzyme of significance in food allergies is trypsin, and to be of significance it

*This work was facilitated by the assistance of the W.P.A. project fund of the University of Wisconsin.
(From the Department of Physiological Chemistry, University of Wisconsin, Madison, Wisconsin).
Submitted June 29, 1938.

must be present in concentrations adequate to account for the rapid digestion of food proteins. All the data indicates clearly that trypsinase is present in traces only. If the food proteins were extensively absorbed, as Oelgoetz asserts, their digestion in the blood would be a very prolonged process.

On the other hand, the evidence presented by Folin (11) and by Van Slyke (12) in 1912 makes it perfectly clear that the digestion of protein in the intestine is rapid and relatively complete, and that the products of such digestion, the amino-acids, are the materials absorbed. There is nothing in this statement, however, to preclude the absorption of such traces of unaltered or partially digested protein material, as Walzer has demonstrated.

What evidence is there that the tissues must be supplied with their hydrolytic enzymes from pancreatic secretion? No direct evidence has ever been produced. Boldyreff (13) originally advanced this hypothesis to account for the disappearance of pancreatic enzymes from the intestine. No tissue enzyme studies were made by Boldyreff, though confirmation appeared at hand in some of the older literature. We have pointed out (14) that the interpretation of this older literature is hazardous, inasmuch as there was no control of the pH of digests at that time, and the characterization of trypsin was necessarily vague. Our own experimentation has failed to indicate trypsin in tissues in more than traces. The typical proteinase of mammalian tissues is cathepsin. Where a trypsinase has been found, it appears referable to the leucocytes (15).

It would be difficult to explain Oelgoetz's statement that heart and brain do not contain the usual tissue enzymes. So far as proteolytic activity is concerned, they have been shown to resemble other tissues (16, 17).

Another unfounded statement is that tissues—other than brain and heart—contain "the serum enzymes in a concentration exactly one hundred times of that of serum." Considering the difficulty in demonstrating even a trace of a trypsinase in liver or muscle, this should make protein digestion in the blood highly problematical.

What evidence is there that feeding pancreatic enzymes leads to their storage in the tissues? Oelgoetz states that feeding a commercial trypsin preparation to rabbits for a week led to doubling liver trypsin and increasing that of the spleen seventeenfold. We have repeated this experiment on 19 rabbits fed for periods ranging from one to six weeks with the same pancreatic preparation recommended by Oelgoetz. Liver, spleen, kidneys and muscle tissue were examined by standard technique (14) for trypsin. Traces of an enzyme acting at pH 7-8 were usually detected. There was no more in the experimental animals than in the controls. We therefore have been unable to confirm the results reported by Oelgoetz.

HOW IS PANCREATIC HYPOFUNCTION DIAGNOSED?

No direct attempt to correlate blood enzyme and pancreatic secretion has been made by Oelgoetz. Instead he describes a test for amylase, and assumes the other enzymes are invariably comparable in concentration to it in the blood. The test is an interesting but crude measure of iodine absorption by the serum. Actually it is not a test for amylase—since the digestion of starch is not measured, and amylase, in

Fig. 1

fact, does not give it. Many other compounds unrelated to amylase do. In the serum, such reducing agents as glutathione, and ascorbic acid will take up iodine, and so contribute to the test. Whether the test measures pancreatic function or not has never been determined. All that can be said of it now is that it is not a test for amylase, and that its significance remains to be determined.

What evidence is there for believing the three enzymes described in blood are invariably present in comparable amounts? Oelgoetz presents a table of figures which show absolutely no variation in the hourly samples assayed for amylase, lipase, and trypsin. Considering the methods used, we must frankly question the reliability of the results. The wide variations recorded by Crandall, Comfort and Osterberg (8, 9, 10) for lipase may be cited as reliable evidence against such constancy as Oelgoetz describes. Boldyreff (13) also found very considerable fluctuations in the blood enzyme concentrations. It might further be pointed out that such constancy of enzyme level, regardless of time of day or ingestion of meals, would itself cast serious doubt on the intestinal origin of the enzymes.

In concluding this discussion, we should like to present in graphic form the proteolytic activity of tissues like liver and adrenals. The experimental details are in press elsewhere (18) and need not concern us here, other than to say the methods used for obtaining the results are recognized as quantitative and reliable.

It will be noted that protein is rapidly and extensively digested at a pH 3 to 4. This is typical of mammalian tissues—including brain and heart—and indicates the enzyme cathepsin. At a pH of 7.5 adrenal gland tissue shows no measurable digestion, although this is close to the optimum reaction for trypsin. We conclude there is no detectable trypsinase present. In the liver, we find a trace of proteolysis at pH 7.5, and we assume there may be a trace of trypsinase. The data does not prove it, since it may be due to the ereptic enzymes known to be present, acting on large molecular protein fragments already present in the tissue at the moment of death, or produced by cathepsin during the preparation of the digests. If we were able to characterize this enzyme more sharply as a trypsinase, the data still does not indicate whether it is derived from pancreas, or as is more probable, from

leucocytes lodged in the gland. The experiment does show how extremely small the activity is which Oelgoetz describes as being 100 times that of the blood.

Finally it may be stated that there is nothing in the soundly based facts of the physiology of digestion which is difficult to reconcile with clinical success in the use of pancreatic enzymes. It is obvious that a deficient digestive mechanism will be slow in the

cleavage of protein, and so may increase the chances of antigenic molecules getting into the blood stream from the intestine. When the clinical evidence establishes the fact of therapeutic value, there will be no difficulty in providing a rational explanation of the observation. In the meantime a hypothesis which ignores established facts, and substitutes assertion for trustworthy evidence should not be taken too seriously.

Pain In Carcinoma of the Stomach: Preliminary Report

By

ANDREW B. RIVERS, M.D.

and

THOMAS J. DRY, M.B.*

ROCHESTER, MINNESOTA

PAIN is one of the most frequent symptoms of intra-abdominal pathologic conditions. Curiously and unfortunately, it is one of the least understood of all of the manifestations of disease. Many of the problems relative to pain will be clarified not by the study of laboratory findings, but rather by the study of data obtained through careful evaluation and correlation of the painful experiences of patients with inspection of the lesions which actually had been responsible for these symptoms. Thus, information of academic importance as well as of clinical usefulness may become available. In the hope that some such information might be obtained, we undertook to study a large series of cases of carcinoma of the stomach. Only such cases were accepted for study in which carefully taken histories were available, fairly definite localization of pain occurred and the nature and extent of the pathologic process had been studied at the time of laparotomy or necropsy. Unfortunately, patients who have carcinoma of the stomach often present themselves for the first time with all of the evidence of a lesion which has progressed to the state of inoperability. In some cases, no evidence of the presence of this disease was available from the history alone.

We are reminded of the instance of one woman who, during the course of routine physical examination, insisted on having a roentgenologic examination of

her stomach performed because she had "a hunch that there might be something wrong there." Roentgenologic examination, in this case, gave evidence of rather extensive carcinoma of the stomach but, even after this information was available, neither were we able to elicit any definite symptoms suggesting the presence of this disease, nor did physical examination in any way suggest abdominal malignancy.

In this paper, it is our intention to discuss briefly a few types of malignant lesions that involve the stomach and to consider how carcinoma of this organ might be productive of the symptom of pain. Before proceeding to the discussion of the mechanics of the production of pain in cases of gastric malignancy, it might be well to review briefly some of the pathways which can be taken by such impulses traveling between the stomach and the patient's consciousness.

PATHWAYS OF PAIN CONDUCTION FROM THE STOMACH

Painful impulses arising in the stomach may originate in the wall of the organ, pass along the sensory bundles in the sheaths of the splanchnic nerves, cross through the white rami communicantes of the thoracic nerves along the posterior roots, and thus reach the posterior horn of the spinal cord. Pain also may be projected to the spinal cord over the sensitive cerebrospinal somatic nerves, branches of which supply the parietal peritoneum, the mesentery of the bowel

*Division of Medicine, The Mayo Clinic.
Submitted May 6, 1938.

and the retroperitoneal tissues. If lesions involve the upper portion of the stomach, some impulses undoubtedly reach the central nervous system through the phrenic nerves. There are several other pathways which may be of some slight importance; these are the ganglionated sympathetic chain or the aortic plexuses from which impulses may reach the spinal cord through the rami communicantes. In all probability, the three more important pathways of conduction are the splanchnic nerves, the sensitive cerebrospinal somatic nerves, and, in cases of very high gastric lesions, the phrenic nerves.

MECHANICS OF PRODUCTION OF PAIN BY GASTRO-DUODENAL LESIONS

It is important to have some conception of the mechanisms involved in the production of pain caused by lesions involving the stomach and it should be mentioned here that there are still many unexplainable phenomena relative to this subject. The discussion of pain arising from involuntary organs demands the consideration of certain fundamental biologic phenomena relative to the phylogenetic development of the nervous system as a whole. In order to evoke the appropriate responses to varying external environmental changes, the surface of the body is endowed with end organs receptive to certain special types of stimuli acting on the body from without. The stimulus evokes a sensation which reaches the brain through afferent nerve fibers. Each type of sensation has its own afferent system of nerve fibers coursing along well known paths in the central nervous system. A stimulus mediating the sensation of pain, then, enables the organism to respond appropriately by carrying out a defensive reaction, the character of which depends on the source and seriousness of the painful stimulus. Similarly, in order to evoke the appropriate responses to varying internal environmental changes, the alimentary canal is endowed with an afferent "pick-up" system receptive, in turn, to certain special types of stimuli to which its environment exposes it. A stimulus mediating the sensation of pain again spells a threat to its integrity and evokes responses accordingly. It is obvious, however, that the high degree of specialization involved will make the stimuli which are adequate for the production of pain on the surfaces of the body more or less meaningless when operative on the gastro-intestinal tract. Tactile sensibility is entirely lacking in the viscera and thermal sensibility is almost lacking; pain cannot be produced by pinching or cutting the abdominal viscera. The presence of disease, however, by causing a disturbance of the function of the organ concerned does supply the adequate stimulus to evoke a sensation which the higher cerebral centers interpret as pain. It is important to realize that sensations resulting from the normal physiologic processes of the stomach are relayed through the same pick-up system to the central nervous system but the sensations so evoked fail to reach the discriminative cortical centers of the brain unless the stimulus is unduly strong, when it again becomes adequate to evoke subjective appreciation.

The adequate stimulus is assumed to be an increase in pressure within gastro-intestinal segments, which results from stretching or contraction of the circular fibers of the viscus. It has been suggested that, in the stomach, this spasm can be the result of hyperacidity which acts as a trigger mechanism that sets in motion

spasm which, in turn, may constitute a stimulus entirely adequate to be appreciated as pain. Furthermore, stretching of muscles or contracting fiber could be incident to bombardment of peristaltic waves against an obstructing or partially obstructing segment anywhere in the bowel. This could be caused by organic obstruction or by functional or sphincteric spasm of any circular muscle.

It is apparent that when lesions progress beyond the confines of the intestine and invade neighboring tissues which are innervated by branches of the spinal sensory nerves, the stimulus adequate to provoke a sensation of pain will be the same stimulus adequate in other regions of the body similarly innervated. Dragging on a mesentery will evoke a painful response, for the same reason.

One of us (1) studied a large series of surgically verified peptic ulcers in order to ascertain the behavior of pain under various histopathologic conditions. This study revealed that a clearly defined uncomplicated ulcer produces diffuse epigastric distress, a purely visceral phenomenon manifesting itself over splanchnic paths only. Obstructing lesions associated with vigorous peristaltic activity produce the familiar colicky pain which again is splanchnic in nature and is felt diffusely in the epigastric region. With invasion in the progress of perforation of the tissues surrounding the wall inhabited by peptic ulcer, it seems to us that the warnings of the traumatizing effect of such invasion would be conducted over the somatic nerves guarding these tissues. Since these nerves are sensitive to many stimuli in addition to the adequate stimulus producing pain along the splanchnic route, a syndrome less rhythmic and less clearly defined than the syndrome caused by uncomplicated ulcer will be produced. Thus, we felt that disturbed syndrome of ulcer, that is, one in which the symptoms are mainly or wholly carried by the somatic nerves, easily could be assumed to have received the predominance of impulses arising outside the wall of the bowel over branches from this system of nerves; whereas, reception of sensations over the plexuses of the splanchnic nerve not distracted by a mixture of impulses arising over the somatic nerves conceivably might be assumed to produce the pain-food-ease sequence so characteristic of uncomplicated duodenal ulcer.

In cases of perforating peptic ulcer a shift of pain from its original site into secondary regions was noted frequently. In cases of duodenal ulcer the characteristic shift of pain was toward the right costal margin; in cases of gastric ulcer, this was usually toward the left costal margin; in cases of jejunal ulcer, the most frequent secondary region of invasion was to the left and along the umbilicus, even extending as far as the inguinal regions. Morley (2) interprets this behavior of pain as the result of impulses received by the sensory spinal nerves and transmitted to the superficial branches of such nerves. This shifting distress he classifies as "referred pain." Regarding the origin of such pains, he stated that "referred pain only arises from irritation of nerves which are sensitive to those stimuli that produce pain when applied to the surface of the body." He assumed that tissues such as the mesentery, mesocolon, and abdominal wall are innervated by the sensory spinal nerves, a presumption which clinical experience would lead us to assume to be entirely reasonable.

THE PHYSIOLOGY OF PAIN AS APPLIED TO CARCINOMA OF THE STOMACH

Palmer (3), in discussing the various factors which he felt entered into the production of pain in cases of carcinoma of the stomach, thought them to be irritation of the pain-producing mechanism by acid, tension of muscles, and, probably, malignant infiltration of the nerve fibers. We believe that the painful symptoms of carcinoma of the stomach utilize for their interpretation conduction pathways and mechanics of the production of pain similar to those which produce pain in cases of peptic ulcer and in cases of lesions of the bowel generally. We can see no pathologic or physiologic reason why this should not be so, and clinical study of a large series of cases of carcinoma of the stomach would seem to bear out the assumption.

The two important methods of the production of pain then would be, first, visceral phenomena utilizing the splanchnic pathway and requiring an adequate stimulus and, second, somatic phenomena which would utilize the spinal sensory group of nerves and requiring only the pain-producing mechanism productive of distress of the surfaces of the body. In order to assume a visceral phenomenon, it would be necessary to postulate stretching or contraction of the muscular fibers within the gastric wall. In the case of ulcers, it is probable that acidity is one of the trigger mechanisms which sets this in motion. Because acidity is frequently low or absent in cases of carcinoma of the stomach, it is clear that the splanchnic phenomenon which otherwise might become a manifestation of this disease probably would be absent. In other instances, particularly those in which acidity is adequate, the distress of carcinoma is indistinguishable from that produced by peptic ulcer. Relief is obtained in the same way and the pain often originates some time following meals, as it does often in cases of benign gastric or duodenal ulcer. This, in all probability, is a visceral phenomenon.

Occasionally, carcinoma of the stomach is productive of gastric retention. This may be owing to several causes, such as actual obstruction at the pylorus or secondary pylorospasm related to lesions anywhere in the stomach. This, again, would be a splanchnic phenomenon which might arise at any time during the digestive cycle.

With the extensive invasion of the gastric wall and perigastric tissues by progression of the malignant lesion, somatic pathways would be invaded. In such instances, pain can be produced even though the adequate stimulus required to initiate the splanchnic phenomenon were lacking originally. It seems particularly noticeable that, when there is evidence of an inflammatory reaction in addition to that of malignancy, such lesions produce more severe pain which includes tenderness and, often a shift of pain into secondary regions, as well as pain occurring at night. On the other hand, it can be seen readily how carcinoma of the stomach might progress to a very serious degree before either the splanchnic or somatic mechanisms of production of pain could be set in motion. The shift of pain into the left shoulder and neck would be the result of a direct invasion of tissue innervated by the phrenic nerve.

SUBDIVISION OF MATERIAL FOR STUDY

In reviewing the histories of the cases under con-

sideration, we tried to subdivide these into several groups. This was done in order to place in separate categories, as much as possible, histories of cases in which similar characteristics regarding symptomatology or pathology were apparent. Group 1 contained cases in which lesions usually were diffuse but were nonpenetrating and nonobstructing. Pain was notably absent. Group 2 contained cases in which lesions were associated with obstruction. Group 3 contained cases in which the lesions were penetrating. This group was subdivided as follows: (a) cases associated with normal or high levels of gastric activity, presenting pain often indistinguishable from that of benign penetrating lesions; (b) cases associated with an inflammatory reaction surrounding the lesion with or without the presence of free hydrochloric acid, and (c) cases without inflammation in the region of the lesion and with low acidity or none. Pain usually was mild or absent. Group 4 contained cases of miscellaneous lesions not classified in the above subdivisions. In a subsequent publication these various types will be considered in greater detail.

REPORTS OF ILLUSTRATIVE CASES

Case history illustrating group 1. Until two months prior to coming to the clinic, this patient had been considered perfectly well. Lately, he had lost weight and strength. Except for vague epigastric distress after eating and marked anorexia there were no other digestive disturbances. The total gastric acidity was 8; hydrochloric acid was absent. Roentgenologic examination revealed extensive carcinoma of the stomach.

At exploration, there was a huge, irregular tumor just proximal to the pylorus, extending along the lesser curvature to the cardia. About the only region not involved was a small portion along the greater curvature at the cardia. Metastatic lesions were not discoverable at operation.

Except for the systemic manifestations this patient had but little to suggest serious organic disease. The vague epigastric distress and the anorexia might well have been of no serious significance. In this case, there was an absence of free hydrochloric acid so that the trigger mechanism which might result in gastric spasm was absent. There was no appreciable inflammatory reaction surrounding the lesion and no obstruction. In this case, therefore, neither somatic nor splanchnic mechanisms of pain would seem to be seriously involved and, consequently, there might well be no local manifestations of the disease. Unfortunately, this type frequently proceeds to the stage of inoperability without the production of any local symptoms.

Case history illustrating group 2. A man, aged sixty-eight years, had lost weight, strength and appetite gradually for a year and a half. Five months prior to examination at the clinic, he had diarrhea for four or five days. For three weeks prior to registration, he complained of gripping midepigastrie pain which was not projected in any direction commencing an hour and a half after meals and relieved by vomiting. The material vomited at times contained food eaten the day before. Nausea and anorexia had become very marked in this period. The total gastric acidity was 36. Free hydrochloric acid was present. One thousand cubic centimeters of gastric contents were recovered by intubation. There was roentgenologic evidence of dilatation of the stomach and obstruction of its outlet.

At operation, carcinoma was found at the pylorus causing obstruction of the outlet of the stomach. Metastasis had occurred to lymph nodes (adenocarcinoma grade 3 on the basis of 1 to 4), but the stomach was freely movable.

This case seems to illustrate a splanchnic type of phenomenon which might be set in motion by any obstruction of the outlet of the stomach. With interference to the normal peristaltic movements, bombardment against the closed pylorus might readily be assumed to produce increased tension or constriction of circular fibers in the wall of the stomach sufficient to produce symptoms. Because of early production of distress and because of the fact that these lesions frequently involve the pyloric region, the degree of operability is usually quite high.

Case history illustrating group 3 (a). A man, aged thirty-nine years, had symptoms dating back three months. He complained of gas and a localized region of epigastric pain the size of a dollar. This pain was projected upward from this region into the thorax, particularly the left side. The pain commenced two hours after meals and was relieved by food and soda. He was awakened by it usually around midnight and again around two o'clock in the morning. Eating eased the pain promptly. There was partial relief when he restricted his diet. The total gastric acidity was 80 and free hydrochloric acid, 68. There was an ulcerating lesion on the posterior wall of the greater curvature on roentgenologic examination.

At operation, a mass 10 by 12.5 cm. was found on the posterior wall of the middle third of the greater curvature; the mass had perforated the transverse mesocolon, requiring excision of part of the large bowel. Partial gastrectomy was performed. Pathologic examination of one of the nodes gave evidence of carcinomatous involvement. Following his discharge, he never regained his strength. Three months later, after an enema, severe hypogastric pain developed, with generalized abdominal soreness and fever. He returned for further examination at which time a diagnosis of generalized peritonitis was made. Meanwhile, a lymph node had become apparent in his axilla which, on biopsy, was found to be carcinoma, grade 4.

The dual mechanism of the production of pain is illustrated equally well in this case. The penetrating features are predictable by the nature of the pain and its characteristic radiation into secondary regions. The gastric acidity was high. In addition to the usual pattern of somatic pain, there is the episode of acute perforation with involvement of the peritoneum and its associated clinical picture.

Case history illustrating group 3 (b). A man, aged fifty-nine years, had symptoms for only one month. These consisted of epigastric pain especially at eleven o'clock in the morning and at four o'clock in the afternoon; partial relief was obtained by taking soda. When severe, the pain was projected through the body to the inferior angle of the right scapula. There was considerable loss of weight and strength. The total gastric acidity was 32, free hydrochloric acid 20. Roentgenologic examination gave evidence of a perforating gastric ulcer on the lesser curvature. At operation, a crater 2.5 cm. in diameter was found, associated with much inflammatory reaction surrounding the ulcer. On pathologic examination it was found to be carcinoma without any apparent involvement of lymph nodes.

This case illustrates adequately the dual mechanism of production of pain similar to that so frequently encountered in cases of penetrating benign lesions of the stomach. First, there is the usual splanchnic syndrome characterized by diffuse epigastric distress commencing late after meals but relieved by food or soda. Second, there is the somatic syndrome resulting from invasion of contiguous tissues innervated by the spinal sensory nerves. The shift of pain into the

region of the right scapula, in all probability is owing to projection of painful sensations along the entire distribution of the particular spinal sensory nerves invaded by the inflammatory reaction surrounding the ulcer. We have, in our series, parallel instances, but with anacidity, in which an inflammatory reaction in regions innervated by the somatic system produced similar symptomatology.

Case history illustrating group 3 (c). A woman, aged sixty-five years, never had experienced abdominal pain except for "soreness of the bowels" of three months' duration and a sense of fullness after a large meal. The total gastric acidity was 20, and free hydrochloric acid was not present. Roentgenologic examination gave evidence of a carcinomatous ulcer on the lesser curvature involving the lower half of the stomach.

At operation, the cancer was found to have perforated into the pancreas and considerable dissection of the pancreas was required to remove the lymph nodes and lesions. Pathologically, it was small cell carcinoma and, above the ulcer, there was a malignant adenomatous polyp. The lymph nodes were not involved.

This case stands in rather interesting contrast to the previous penetrative lesions, in that pain was very much in the background despite quite considerable penetration into adjoining viscera. It can be assumed that all of the factors necessary to condition the adequate stimulus were not present and it can be affirmed rather strongly that acidity is one of those factors.

SUMMARY

In this paper we have attempted to outline in a general way the important pathways of conduction of pain from, and mechanics of production of pain in, the viscera in the upper part of the abdomen. The general principles involved follow a pattern similar to that encountered in cases of benign lesions of the stomach. We felt that, if gastric carcinoma superficially invades the tissues of the stomach and results in disturbances of its normal mechanics, pain may result. This pain would utilize pathways coursing along the splanchnic vessels. In order to be interpreted as pain, these irregularities in mechanics would require an "adequate" stimulus which, in this case, would be spasm or obstruction. If, on the other hand, the lesion burrows through the gastric wall into the tissues surrounding the organ, pain would be relayed to the spinal cord over the spinal sensory group of nerves and, in this instance, wide distribution and reference of pain may be produced. If the lesion invades the regions of the distribution of the phrenic nerve, pain will be referred into the left side of the thorax and to the "peripheral distribution" of this nerve which would be into the left shoulder and the base of the neck. Such a lesion is usually inoperable. Any stimulus which would initiate the sensation of pain on surfaces of the body also could produce pain in penetrating lesions.

Applying these hypotheses to the problem of pain in cases of cancer of the stomach permits an explanation of the apparent paradoxical behavior of distress among patients harboring such lesions. Who, at operation or necropsy has not viewed with surprise tremendous cancers involving most of the stomach which have produced no pain whatsoever? After all, this should be no more the cause of astonishment than to witness surgical procedures on the stomach which caused patients no pain even though only local anesthesia was used. The mechanisms which produce pain in such cases depend on the production of an adequate

stimulus, such as stretching or constriction of the circular muscular fibers which would require a mechanical disturbance, such as spasm or obstruction. If cancer does not set in motion this adequate stimulus, it is likely to produce no pain whatsoever. If, on the other hand, there is mechanical disturbance such as interference with normal emptying or invasion of the pylorus, pain or at least a sense of epigastric distress is likely to be one of the earlier manifestations of this disease.

Cancer of the pylorus therefore is more often amenable to surgical treatment than are other types of cancer, not only because of its resectability from a physical standpoint but because of the fact that, as a rule, it produces symptoms relatively early. Shift of pain from original to secondary regions among patients who have cancer of the stomach is of varying significance. In the event that the lesion is small, for instance, a penetrating peptic ulcer harboring in its depth malignant degeneration associated with hyperacidity, a shift of pain may not be of very serious significance. If, on the other hand, the lesion is fairly extensive and the patient complains of shifts of pain from the original into secondary regions, the lesion will be found to be inoperable in almost all instances. This, of course, is owing to the fact that cancer has penetrated the wall of the organ and has invaded tissues contiguous to the stomach. The shift of pain, in such instances, is owing to invasion of the spinal sensory nerves.

In a general way, it can be said that cancer of the stomach in which gastric chemistry is normal or is elevated is much more likely to produce a painful

syndrome than that in which there is no acidity or only a trivial amount of hydrochloric acid. This is probably owing to the fact that the acid acts, as it does in cases of benign gastric lesions, as a trigger mechanism which initiates spasm and this, in turn, is responsible for the sensation of pain. Otherwise stated, with the exception of pyloric lesions which cause early obstruction, the presence of carcinoma of the stomach is suspected most usually by its complications and its systemic effects when the lesion has advanced beyond the bounds of operability.

CONCLUSIONS

1. Splanchnic phenomena in cases of carcinoma of the stomach do not cause dramatic effects unless obstruction is present. Thus, even extensive cancer of the stomach may not produce pain, particularly if free hydrochloric acid is present in small amounts or is absent.

2. Somatic phenomena are prominent but because they depend on penetration of the lesion beyond the confines of the bowel, symptoms are delayed until such extension has occurred. For this reason cancer associated with pain referred to the thorax or back, or along the distribution of the phrenic nerve is usually inoperable. The presence of either free hydrochloric acid in the gastric contents or an inflammatory reaction in the vicinity of the lesion, or both, may accentuate somatic pain.

The Effect of Acetyl-B-Methyl Choline (Mecholyl) on the Gastric Secretion in Animals and in Man*

By

JAMES FLEXNER, M.D.

and

IRVING S. WRIGHT, M.D.

NEW YORK, NEW YORK

THE action of acetyl-B-methyl choline chloride (mecholyl) on the gastric secretion was first studied by Abbott (1). He determined the volume and acidity of the gastric secretions in 9 human subjects after mecholyl in dosages of 200 to 300 mgm. orally and 5 to 10 mgm. subcutaneously. In most cases there was a slight to marked increase in acidity and in no instance was there a marked decrease in gastric acidity. There was an increase in acidity in 3 of 6 cases of hypochlorhydria, but he felt that histamine was more useful for this purpose.

Ferguson and Smith (2) were the next investigators to report on the effect of mecholyl on gastric acidity. They reported the abolition of free gastric acidity in monkeys when a sufficiently large dose of

mecholyl was administered subcutaneously. In their cases the total acidity paralleled the free acid curve but the total chlorides were unaffected. The mucous secretions were increased, particularly, the saliva.

Myerson (3) and his co-workers published a report on the changes in gastric secretion in physiologically normal human subjects following the injection of 20 to 30 mgm. of mecholyl subcutaneously. They claimed that there was a "diminution or disappearance of the digestive secretions, hydrochloric acid and pepsinogen, and finally, the appearance of mucin." They reported similar findings with mecholyl by iontophoresis and these observations were recorded in a later communication (4). They felt that Abbott had failed to use sufficiently large doses of mecholyl and thus explained the diametrically opposite results.

Schnedorf and Ivy (5) in a recent publication found that mecholyl caused acid secretion in previously an-

* Work was made possible by a grant from Merck and Company, Rahway, New Jersey, who also supplied the mecholyl.
Department of Medicine, New York Post-Graduate Medical School and Hospital, Columbia University, New York.
Received May 6, 1935.

acidic monkeys. They also reported that these monkeys gave an acid response to histamine after mecholyl injection where they had failed to get such a response before.

It is apparent from these reports that the issue was confused. Two groups of investigators working with monkeys reported opposite effects of mecholyl on gastric secretion; two other groups working with human subjects also disagreed.

In our work on the effect of autonomic drugs on the gall bladder (6) and hepatic secretion (7), we were impressed by the marked mucinous salivary response to mecholyl. This result was obtained in human subjects and cats regardless of whether mecholyl was given by injection or iontophoresis. The gross physical similarity of specimens obtained on gastric or duodenal drainage to the saliva was striking. We also found that anaesthetized cats had a definitely respiratory type of death on certain mecholyl dosages and on postmortem examination the lungs showed the changes characteristic of drowning. These same dosages, however, were readily tolerated if a tracheal cannula was inserted prior to the mecholyl administration. Thus it was obvious that these deaths had been caused by drowning in aspirated saliva and that bronchial secretion and spasm were unimportant factors.

Abbott (1) was the only one of the previous investigators to specifically state that precautions were taken against swallowing saliva. We devised the following experiments to determine what influence swallowed saliva had on the results obtained by other of these investigators.

EXPERIMENTAL FINDINGS

Animal Experiments

Rabbits varying in weight from 2.5 to 3.5 kilograms

were anaesthetized by the intraperitoneal injection of sodium amytal (75 mgm. per kilo.). A tracheal cannula was inserted. A No. 18 Levine tube was passed into the stomach through the mouth in some; through an opening in the portion of the esophagus below the diaphragm in others. In the latter group another tube was passed partially up the esophagus and in some cases a tube passed through the mouth to meet the tube ascending the esophagus. Gastric specimens were collected before and at intervals after the subcutaneous injection of 2 and 4 mgm. of mecholyl. The volume of each specimen was recorded and the free and total acidity determined by titration with .02 N sodium hydroxide using Topfer's reagent and phenolphthalein as indicators. The gastric secretion was continually tested with congo red paper.

Because of the persistent gastric residue in rabbits an accurate determination of the change in gastric secretion was not possible. The gastric secretion was always positive with congo red paper and there was no evidence to suggest the outpouring of alkaline and mucinous gastric secretion in any great amount. A large amount of saliva was secreted into the oral cavity but this did not reach the stomach in the anaesthetized rabbit with or without a tube passing down the esophagus.

Because of residue which was a handicap in the experiments with rabbits the experiments were repeated on cats. Three cats (weight 3 to 3.5 kilograms) were anaesthetized by intraperitoneal injection of sodium amytal (75 mgm. per kilo.). In all three the gastric contents were found to contain no free hydrochloric acid on fasting and the condition persisted after subcutaneous injections of 2, 4 and 10 mgm. of mecholyl.

Human Experiments

A Levine tube was passed in human subjects and each patient placed on his right side. All of the fasting content was aspirated, the quantity noted, and tested with congo red paper for hydrochloric acid. An emesis basin was placed at the side of the patient's mouth and he was urged to expectorate all the saliva and to avoid swallowing.

mens were analyzed for free and total acidity, by the method stated above, and for amylase activity by the method of starch hydrolysis and sugar determination. The total volume of the saliva and its amylase activity also were determined. This experiment was performed 5 times on 3 patients. Later the above experiment was repeated with these same and other patients lying on the abdomen with the head low. A mouth gag was inserted to prevent swallowing? These precautions precluded any chance of the saliva being swallowed or draining into the esophagus. Seven experiments with these modifications were carried out on 4 subjects.

It is apparent from the Table I and Figs. 1 and 2 that when the patient lies on his side there is a decrease in free acidity which promptly follows the injection of mecholyl. The free acidity completely disappeared in 4 out of 5 experiments and the secretion also changes from serous in character to a ropy, mucinous fluid. The actual volume changes of the aspirated gastric secretion are necessarily inaccurate because of frequent duodenal regurgitation and occasional incomplete evacuation due to mucosal plugging of the Levine tube. When the patient is placed on his abdomen, however, and precautions taken against swallowing saliva there is an equally prompt rise in free acidity with a flow of serous gastric juice following a similar injection.

Gray and Ivy (8) had reported a reversal effect on the gastric secretion in gastric pouch dogs. These dogs had both vagi cut and were given continuous injections of histamine until the gastric secretion was constant in volume and acidity. Then the subcutaneous injection of 0.1 mgm. of mecholyl caused an increase in gastric secretion while 1 mgm. similarly injected caused a decrease in acidity. These investigators felt that this reversal explained the alkaline gastric secretions following large injections of mecholyl observed by Myerson and Ferguson and Smith.

We feel that it is evident from our experiments that 25 mgm. of mecholyl injected subcutaneously in human subjects has caused neither a marked decrease in degree of free hydrochloric acid nor a marked change in character or volume of the gastric secretion when care is taken to prevent the swallowing of saliva. It is clear that when a marked change is recorded that it is due to swallowed saliva. This fact is established by the almost identical

degree of the amylase activity of the saliva and the gastric secretion on several occasions when they were simultaneously collected; it is further borne out by the changes in total volume of the saliva, collected after the mecholyl, in the same patients, when studied under identical conditions, except those modifications designed to prevent the swallowing of saliva.

The saliva of the human subjects was studied on several occasions. It was found to change in its reaction to litmus paper from slightly acid on fasting to alkaline following mecholyl injection. On titration with .02 N sodium hydroxide the total acidity was observed to change from 12 to 4 in some instances and there was in each case a decrease in total acidity. The great increase in thick, ropy mucin probably acts as both a diluent and buffer. The value of this buffer mechanism was demonstrated by mixing in vitro various amounts of gastric secretion of known free and total acid concentration with the alkaline saliva. In these mixtures there was a greater decrease in free acidity than the dilution factor, while the total acidity decreased more nearly in proportion to the dilution. This greater decrease in free acidity is a crude indication of the buffer value of the saliva. The great viscosity, tenacity and incomplete miscibility of the saliva may account for the variation from the predicted decrease in total acidity.

It appears from our studies that while mecholyl injected in this dosage usually caused a slight to marked increase in gastric acidity, unless great care was exercised enough alkaline, mucinous saliva was swallowed to buffer the gastric secretions. It, therefore, seems that if all the saliva is purposely swallowed an efficient buffer may be available for use in cases of gastric hyperacidity. The clinical application of this principle is being investigated.

CONCLUSIONS

1. There was no outpouring of mucinous, alkaline gastric secretion in 6 rabbits after subcutaneous injections of 2 and 4 mgm. of mecholyl chloride.
2. There is no marked change in the free and total

FIG. 2*

EFFECT OF MECHOLYL ON FREE ACIDITY OF GASTRIC JUICE IN HUMAN SUBJECTS WHEN SALIVA IS NOT SWALLOWED.

acid of the gastric contents in rabbits after these dosages but because of large amounts of solid gastric residue these figures are not wholly accurate.

3. In 3 cats no free hydrochloric acid was present in the fasting gastric specimen nor did any appear after subcutaneous injections of 2, 4 and 10 mgm. of mecholyl chloride.

4. When proper care is taken to prevent the

swallowing of saliva there is no marked change in character in the gastric secretions in human subjects following the subcutaneous injection of 25 mgm. of mecholyl chloride.

5. There is in most instances a slight to marked rise in free and total acidity following such an injection.

6. There is a marked increase in flow of saliva which becomes mucinous and more alkaline.

7. The accidental swallowing of less than one-half of the saliva more than neutralizes the rise in gastric acidity and the purposeful swallowing of the entire

amount is suggested as a possible therapeutic measure in cases of hyperacidity.

History and Development of Gastric Analysis Procedure*†‡

By

FRANKLIN HOLLANDER, Ph.D.

and

ABRAHAM PENNER, M.D.

NEW YORK, NEW YORK

I. INTRODUCTION

GASTRIC analysis is used today almost universally as an aid in diagnosis. Nevertheless, there is an exceedingly widespread dissatisfaction with it, amounting with many individuals and institutions to a forthright negation of all but a modicum of diagnostic significance. Why is this so, and what does it portend for the future of gastric analysis? And what, if anything, can be done about it? As workers in a research laboratory devoted entirely to gastro-intestinal physiology and its clinical applications, we realized that this is one of the foremost problems which we face today. The matter is vital because every effort at studying gastric physiology in the human—both normal and pathological—must ultimately be based on the procedures of clinical gastric analysis.

Hence, we started last year a series of investigations in an effort to work out a procedure which may prove more satisfactory to clinicians and research workers alike. For this purpose it was essential to have sharply defined in our minds the present trends in gastric analysis procedure. The latter, in turn, necessitated a thorough historical survey of the problem in all its phases, in order that we might attain some historical perspective on our subject. A search of the gastro-enterological literature of the last 60 years yielded enough material for a monograph rather than a short paper on the subject. Hence the present report will be devoted chiefly to the criticisms which have been leveled against present procedures and to the developmental trends which are already discernible in response to these criticisms.

Taking an airplane view of the entire span of gastric analysis procedure, we perceive four well-defined periods of development. These periods may be characterized as follows:

1. The primitive, non-diagnostic period (up to 1883)
2. The single specimen, diagnostic period (1883-1914)
3. The fractional analysis period (1914 to date)
 1. A period of physiological analysis.

These subdivisions are clearly differentiated by the development of a new technique in each case, yet it must be noted that chronologically they overlap to a considerable degree. Thus the primitive period gave way to the early diagnostic period with the introduction of a well-defined test-meal and the rubber stomach tube; fractional analysis, in turn, was made possible by the development of the fine, soft rubber catheter; the modern trend away from a search for simple clear-cut diagnostic procedures and toward an analytically physiological view of the patient is characterized by a statistical outlook. The extent to which the individual periods overlap in time will become apparent as we proceed.

II. THE PRIMITIVE, NON-DIAGNOSTIC PERIOD (UP TO 1883)

Interest in the secretory products of the gastric mucosa was but sporadic until relatively recent times. Robertson (113) quotes Van Helmont (1648) as writing of an acid ferment responsible for digestion. In 1692 Viridet obtained gastric juice for gross study by killing animals for this specific purpose. Sixty years later (1752) Reaumur studied the gastric juice of birds by inserting a sponge into the stomach and expressing the juice after its withdrawal. Human gastric juice was first studied carefully by Reuss (1760) in instances where it could be obtained from individuals capable of vomiting on request.

These studies belong to the archaic period of the study of gastric secretion, which preceded the discovery of hydrochloric acid in the stomach by Prout in 1821. Not until 1833 do we encounter the first experimental efforts on humans in the classical studies on Alexis St. Martin; and ten years later the experi-

‡Submitted June 20, 1938.

mental approach in gastric physiology was initiated by Bassow and Bloudot who duplicated the St. Martin gastric fistula in animals. Thereafter, forty years were to pass before human gastric juice became readily available for careful study. During this period the first lines of analysis of the problems of gastric secretion were gradually laid down on the basis of animal experimentation by Klemensiewicz and Heidenhain. It was during this period, also, that technical advances in the vulcanization of rubber—initiated by Charles Goodyear in 1844—first made possible the clinical use of the stomach tube.

The stomach tube owed its introduction into medical procedure to its therapeutic possibilities rather than its applicability to diagnostic medicine. According to Garrison (48) the principle and practical application of the stomach tube, or stomach pump, probably evolved before 200 B.C. Its utility in withdrawing ingested poisons was recognized by Monroe Secundus in 1767, and John Hunter (1790) utilized it to feed a patient with an esophageal obstruction. In this country it was first used by Physick, who employed it for purposes of lavage in cases of poisoning.

A further and important extension of its use is due to Kussmaul (1869) (74) who aspirated the stomachs of patients with pyloric obstruction due to duodenal ulcer, thus affording symptomatic relief and prolonging the lives of many of them. Despite the frequency with which he obtained gastric juice by means of these aspirations, his interests were so obviously therapeutic that he apparently never examined the contents chemically and he recorded only the morphological elements and the gross physical characteristics of the fluid. However, as a result of the work of so famous a clinician from an internationally known clinic, the therapeutic application of the stomach tube soon became very popular.

III. THE SINGLE-SPECIMEN, DIAGNOSTIC PERIOD (1883-1914)

It was only four years later, in 1883, that the possibilities inherent in the stomach tube for diagnostic purposes were first reported. In this year von Leube (77) aspirated stomachs after ingestion of a standardized meal—primarily for the purpose of determining the amount of residue but also to determine the concentration of acid and pepsin. His interests were chiefly those of a physician interested in gastric diagnostics, and as such he devoted his attention to the degree of digestion of the test-meal as well as to the amount which remained in the stomach after a given time interval. In this way he thought to obtain a picture of the digestive and motor capacities of the stomach in various disorders.

This elementary physiological point of view, which was lost for several decades but is now cropping up again, is based on the following reasoning: The composition of the gastric contents at a given time is dependent on a large number of interrelated variables. It is obvious that the most important extra-gastric factors which determine this composition are the stimulus (i.e., the test-meal) and the time interval between its application and removal of the specimen. With these factors kept constant, the only uncontrolled variables presumably were those inherent in the status of the gastric mucosa, and thus the result of the test would reflect the pathological changes in these variables and so yield information of diagnostic value.

For a standard gastric stimulus, von Leube used a mixed meal consisting of beef bouillon, a beef steak, pureed potatoes and one slice of white bread. This was ingested in place of the usual noon meal, and after a seven hours' fast the gastric residue was aspirated and examined for food residues as well as for the presence of acid and pepsin. In this fashion he was able to evaluate the motor function of the stomach as well as its capacity to secrete in response to a standard test-meal.

Despite von Leube's interest in the secretory phenomena, his main objective was to establish the emptying capacity of the stomach—in which he undoubtedly succeeded from the practical point of view. For the purpose of testing gastric motility, von Leube's test meal was very satisfactory. He performed only a single aspiration; probably that was all that could be tolerated by his patients because of the large, stiff tube which he used. In spite of this, the technique became extremely popular on the continent, due in no small measure to the efforts of Ewald, Boas and Riegel at further standardization and simplification of the test-meal. Beyond such changes in the nature of the stimulus, and the reduction in time interval from 7 hours to 1 or one-half hour, these latter investigators contributed very little to the procedure introduced by von Leube—although their studies were numerous and well conducted. Concerning the nature of these test-meals more will be said later.

As early as 1891, however, the need, for clinical purposes, of a more dynamic picture of the course of the secretory, digestive and motor characteristics of the stomach began to be realized. In that year Hayem and Winter (56), using the Ewald-Boas test-meal and the tube in vogue at that time, aspirated gastric contents of fasting patients; aspirations were performed at 30 minute intervals after the administration of the test-meal until the stomach was empty. They plotted curves of free, total, and combined acidity and thus succeeded in combining the chemical and motor test-meals in a single examination. In 1895 Schüle (121) performed a similar study in which he reduced the interval between aspirations to 15 minutes. These were the sole studies of their kind until the twentieth century when advances in rubber technology made it possible to create a tube which could be more readily used for this purpose.

IV. FRACTIONAL ANALYSIS PERIOD (1914 TO DATE)

The need for a simple method of following the course of gastric secretion and digestion could be met only by the development of more flexible tubes of smaller caliber, than those employed by von Leube, Ewald, etc. Although Gross (55) used such a tube in 1893, it was not until 1912 that its systematic use became general. In that year Ehrenreich (35) using such a flexible, narrow rubber tube with the Ewald-Boas test-meal, followed the example of Winter and Hayem and of Schüle and withdrew small specimens for analysis at 10 minute intervals following ingestion. The procedure did not become popular, however, until 1914 when Rehfuss (110), in this country, described his well-known tube. With this innovation, one may say that the modern period of gastric analysis was truly under way. In the years that followed, the tube was modified by numerous investigators, such modifications usually involving the shape, size and

fenestration of the tip. An extensive historical review of the various modifications may be found in a recent article by Moses Einhorn (37). In all essentials other than the composition of the test-meal the principles and procedures established by Rehfuß have remained unchanged, until this very day.

The usual tube is about 1 meter long with an outer diameter of 6-7 millimeters. Its tip is formed by a stainless metal (gold-plated) bucket. The tube is marked off at 50, 65 and 80 centimeters from the tip and it is usually introduced to the 65 centimeter mark for gastric analysis. The test-meal varies with the preference of the clinician. It is worthy of note that the modern period of fractional analysis has concerned itself mainly with secretory phenomena and only to a lesser extent with the motor activity of the stomach. One manifestation of this is the fact that the noon and evening test-meals have virtually been discarded and only a breakfast test-meal is now employed.

Apart from the nature of the test-meal stimulus, the procedures involved are always essentially the same. The tube is swallowed while the patient is in the fasting state, and special attention is given to the complete expectoration of saliva. The fasting contents are aspirated and set aside for chemical analysis, after noting its gross physical characteristics such as volume, color, odor, presence of mucus, blood, or bile. The test-meal is then administered, either by ingestion or by passage through the tube, and at regular intervals thereafter specimens are removed for chemical analysis. This may be done in either of two ways:

(1) The procedure employed by Rehfuß, which is to withdraw only 10-15 cc. each time.

(2) A modification introduced subsequently, whereby the entire contents of the stomach is removed each time, mixed thoroughly, and all but 10-15 cc. returned through the tube. In either case the procedure is continued until the stomach is empty. In aspirating, only the gentlest of suction is applied, with the aid of a glass syringe, in order to avoid trauma.

The failure of the single specimen type of gastric test-meal to yield accurate diagnostic information was felt even by the earliest workers. Even Hayem and Winter, and Schüle felt that although the composition of the gastric juice obtained one hour after the ingestion of a test-meal had considerable practical significance, the results were frequently indecisive and difficult of interpretation. Also, the problem of gastric activity presented a two-fold aspect: a secretory and a simultaneous motor. It was in order to study the variations in intensity of these two functions throughout the course of digestion that they conceived the idea of the fractional test meal.

The concept basic to these newer efforts, never explicitly formulated by these early workers, was that whereas variations from normal gastric function might not be readily discovered by means of the single specimen technique, the fractional method was capable of demonstrating pathological variations in the ability of the diseased gastric mucosa to respond to a standard stimulus. It was hoped that such variations in the response of the gastric mucosa to a standard stimulus would prove to be representative of its working capacity, and hence would permit a classification of gastric secretory behavior. Amplification of this idea culminated in the formulation of the several categories of secretory activity, characterized by the degree of acidity and of pepsin activity attained by

the several fractions removed in the course of a single analysis. These categories possess the now universal designations of hyperchlorhydria, isochlorhydria, hypochlorhydria, achlorhydria, and achylia. Another classification, designated hyper-, hypo-, and apepsia is now obsolete. Emptying time, when it was considered at all, was characterized as hyper- or hypomotile by the time required for the test-meal to disappear from the stomach. With the creation of such divisions, based on the quantitative measurements of time and acidity, efforts were made to correlate the various gastric disorders with these classifications. In this way it was hoped that the procedure of fractional analysis would yield information concerning the physiological components of gastric pathology, just as radiographic and gastroscopic examinations demonstrate the anatomical components.

With the introduction of the small caliber tube into clinical work by Rehfuß, there ensued a wave of enthusiasm for the diagnostic value of the procedure. The ease with which the analysis could be performed was especially potent as a factor in its universal adoption. Shortly after its initial acclaim, however, various criticisms began to be leveled at the procedure from different directions. The bases of these criticisms may be summarized as follows:

(1) The stimulating action of the tube itself on the gastric mucosa, merely by mechanical action.

(2) Dilution and neutralization of the gastric juice by saliva.

(3) The psychic effect of the presence of the tube in the mouth and throat.

(4) Dilution of gastric juice by the test-meal.

(5) Variations in composition of the gastric contents at different levels in the stomach.

(6) Irregular duodenal regurgitation, resulting in dilution and neutralization of the stomach contents.

(7) Variation in secretory response ascribable to differences in composition of the test-meal stimulus.

(8) Wide day-by-day variations in the type of curve obtainable with any one "normal" individual; and the occurrence of "normal" curves in cases of obvious gastric disease, and of "abnormal" curves in healthy individuals.

With the exception of the last, all of these criticisms were met by Rehfuß and his associates by the following argument. It is the presumption of these criticisms that the aim of a fractional analysis is to give a picture of the secretory activity of the stomach. This is not so. To quote Rehfuß himself (110), it is to study the entire work of the stomach and, by correlating its manifestations with gastric pathology, to set up a diagnostic test in terms of this work. By the work of the stomach he meant the result of all the numerous processes which operate in "the reduction of a heterogeneous mixture of foodstuffs into a homogeneous chyme." The summation of all these processes, he contended, is adequately indicated by the acidity curve, the degree of chymification, the emptying time, and the visual evidences of pathology obtained by gross and microscopic inspection.

The last criticism, however, the basis of which may be summarized by the expression "normal biological variation," could not be coped with by Rehfuß. How can we hope to classify disease on the basis of a particular test when the responses of normal and diseased stomachs to that test are not constant and quanti-

tatively distinct from each other—in short, when there is no correlation between pathology, roentgenographic observations, and the chemical results of the fractional analysis. For this reason more than any other, the hope of clinicians that fractional analysis would afford a simple diagnostic procedure was doomed to failure.

In spite of their cognizance of this failure, many gastro-enterologists have continued to use the fractional technique. This may be due in part to lingering hopes, and in part to the feeling that the Rehffuss method remains a valuable aid to diagnosis. The numerous and continued efforts at refinement of the fractional technique which are apparent in the literature, however, betoken something far more important; namely, that the procedure is gradually being transformed into an instrument of precise physiological research concerning the individual component elements of gastric behavior. The modern clinician is becoming aware that there is no short road to diagnosis and that he can understand his patient only by comprehending the latter's individual physiological responses. This, we believe, is the beginning of a new scientific period in clinical gastric analysis. Before discussing it, however, we must first describe the historical development of test-meals and of the chemical-analytical methods which are employed today.

V. TEST-MEALS

Of all the many test-meals which have been and still are employed for gastric analysis, the "test breakfast" proposed by Ewald and Boas (41) in 1886 takes precedence as a standard. Previous to this (1883), we find the following mixed meals which were proposed for the study of emptying time or of digestive activity, in contradistinction to secretory activity *per se*. The "dinner meal" of von Leube (77) consisted of soup, beef steak and white bread, and was aspirated after seven hours. A similar mixed meal consisting of veal, white bread, and other foodstuffs was employed by Ewald and Boas (40) in their early work (1885), but it was soon discarded for the similar "test breakfast" as we now know it. About the same time, Riegel (112) used a mixed meal of 400 cc. of soup, 200 gm. of beef-steak, 50 gm. of white bread, and 200 cc. of water; this also was aspirated for examination seven hours after ingestion. The mixed "evening test-meal," proposed by Boas in 1894 (14) was also intended to be chiefly a test of motor sufficiency; but because of its inadequacy it was subsequently improved by the addition of a tablespoonful of currants (Strauss (130)), six prunes (Bourget (19)), or 1-2 grams of bismuth subcarbonate (Robin (114); Grandauer (54)).

The Ewald meal as it is used by various workers today—which differs from these others in being designed for secretory as well as motor studies—varies widely in its composition. It may consist of any one of the following solid foods, accompanied by a fluid; bread, white bread, toast, rolls, sweetened or unsweetened crackers of various kinds—all either buttered or unbuttered and in quantities which vary from 30 to 70 grams. The fluid portion of the meal may be either water or tea (without sugar and cream), in volumes which vary from 200 to 500 cc. According to Lyon (84), however, Ewald himself used 50 grams of bread or roll and 350 cc. of water, but in their original paper Ewald and Boas used 35 grams of white bread with two glasses of tea or 400 cc. of water. Numerous

modifications of this meal have been introduced because it is non-palatable and does not develop psychic secretion, e.g., arrow-root cookies as used at the Mayo Clinic (Eusterman and Balfour (39)) and shredded wheat biscuits or soda crackers as recommended by Crohn (26) for office use.

From the very beginning these dietary test-meals found disfavor among clinical workers because of their complexity, and especially because of their content of solid substances. Also, reliable determinations of acidity in these mixtures were well nigh impossible unless each fraction was filtered, but this also introduced an error because of the difference in titre before and after filtration (Pfaundler (104), Vos (138)). Hence, in an effort to use a dietary substance which is entirely fluid, Talma (133) in 1895 administered through the stomach tube 3 per cent Liebig's extract which had previously been neutralized with NaOH. Since then this meat extract preparation has been employed in various concentrations and volumes by numerous investigators (Mintz (95), Skaller (127), Lewin (80), Martini and Beck (87) and Wilhelmj (139)). Similarly, the original oatmeal test-meal of Boas was made popular in this country by Crohn and Reiss (27) in 1917; four years later Ryle (116) introduced it into England. In 1910, Fuld (44) proposed a solution of caramel, 1 tablespoonful in 200 cc. of water; and in 1928, Orlawsky (100) used a drink containing cabbage juice—but neither of these has found very wide application. In a desire to use a pure chemical substance which is also, to some extent, dietary in nature, Kast (67) proposed the use of alcohol in a concentration less than ten per cent, since at this dilution acid but no mucus is stimulated. It was not until 1912, following its use by Ehrmann (36), that the alcohol meal became really popular and was used by such notable workers as Killing (71), Wonkhaus (145), Katsch and Kalk (68), Bloomfield and Keefer (12), and Vandomfy and Varády-Borbély (136). In spite of its very extensive use, however, the claim has been made repeatedly that alcohol is non-physiological and irritating—both of which contentions may be questioned—and hence should be abandoned. As a substitute for it, Katsch and Kalk (69) introduced the use of caffeine which they believed to act directly on the secretory glands; in this they probably followed Strauss (129) in his use of tea for its caffeine content. This substance has also been used by Schwab (123), among others, but as yet it has not become popular. It must be noted that, for any one of these various test-meals, the volumes and concentrations employed by the several workers who used them show considerable differences.

In contradistinction to the dietary motor test-meals previously described, the fluid test-meals were introduced with a view to evaluating the secretory response of the patient. Hence, the question naturally arises: How do these several fluid test-meals compare with each other in respect to their stimulatory activity? This problem has been carefully investigated in several laboratories, using the fractional technique, and the results indicate that 5 per cent alcohol, bouillon, tea and caffeine all give essentially the same results (Dinkin (32), Garbat (47)). What lack of agreement was observed may well be attributed to the normal daily variation of the patient or to the variations involved in the removal of individual specimens during any one analysis. Furthermore, comparison of these test-meals

with plain water, cold or warm, tap or distilled—a test-meal first proposed by Bergeim, Rehfuß and Hawk (10) and used by Moffatt, Mitchell and Powell (96) without any stimulatory results—suggested that the special test substance in each case was contributing nothing to the stimulatory action of the water itself. Hence, in spite of Crohn's preference for a food substance because of its slight gustatory attractiveness (26), it would seem that the plain water serves all the functions of these other test-meals; and since it is mechanically and chemically simplest of all, it would appear to be the one logical substitute for the purposes of gastric analysis. This conclusion may be objected to on the ground that plain water serves only as a mechanical stimulus to secretion and not as a chemical stimulus (Lim, Ivy and McCarthy (82)). But if the special chemical stimuli present in these various test-meals are contributing little or nothing to the secretory process, as appears likely from the observations reported, then why use them at all? This question cannot be answered now, but it is certainly one which merits experimental consideration.

From time to time fluid test-meals have been objected to because their emptying time, in general, is considerably less than those reported with the Ewald meal; sometimes it is even less than 45 minutes (Garbat (47)). Also, it is claimed by many workers that duodenal regurgitation is much greater with a fluid meal than with a solid one, but this difference may be entirely illusory because of the presence of the bread much in the latter. (Dinkin (32), Garbat (47), Gaither (45)). On the other hand, they point out a number of distinct advantages possessed by fluid meals: (1) They are homogenous and contain no sediment which might interfere with studying the cellular elements or in titrating. (2) They are free

from alkaline salts which might reduce the total acidity values, and some of them have no effect on the free acidity either. (3) They can be removed more easily through a small duodenal tube than a bread-containing mixture. (4) Above all, they permit of a degree of standardization and of purity such as cannot possibly be attained with a food test-meal.

Unfortunately none of the fluid meals give any reliable indication of the emptying time in those cases which show retention for one hour or more. In the case of the Ewald or other food-containing test-meals, the amount of meal retained after, say, one hour was usually taken as an index of emptying time. With the use of fluid test-meals this criterion is frequently impossible; to offset the difficulty, it has been proposed from time to time that a small amount of some colored substance be incorporated before administration, in much the same way that raisins and currants were added to solid meals. To this end Ehrmann (36) used a few drops of methylene blue, Boas employed chlorophyll, Skaller (127) introduced phenolphthalein (which becomes colored on alkalization) and Lewin (79) a few drops of phenol red. Absence of indicator substance noted by qualitative examination of successive specimens indicated the time at which the last traces of test-meal had left the stomach, i.e., the emptying time.

In view of the possibility that minute amounts of the indicator may adhere to the gastric wall for some time after the bulk of the test-meal passes through the pylorus, we believe that such a qualitative technique is unsatisfactory. Instead, the situation calls for a quantitative evaluation of the test-meal residue in each fraction—a procedure which we will discuss more fully below.

(To Be Continued)

Peptic Ulcer---The Effect of High Protein Diet on the Behavior of the Disease*

By

CHARLES WINDWER, M.D.

and

MILTON J. MATZNER, M.D.

BROOKLYN, NEW YORK

ON a theoretical basis a high protein diet should favorably influence the symptom-complex of peptic ulcer. Proteins can neutralize acids by their acid-binding properties. Peptic activity can be inhibited by the acid-combining properties of proteins or by the "competitive retardation" of the products of peptic digestion of proteins. Again, proteins supply ample amino acids and would restore a deficiency believed by many to be a causative factor in the production of peptic ulcer.

High protein diets have been advocated in the past by Lenhartz, Wagner, Kaufman and others (1). With the advent of the Sippy regime of milk and cream, frequent feedings and alkalies, the protein diet lost its popularity.

*From the Gastro-Intestinal Clinic of the Jewish Hospital of Brooklyn, Dr. B. M. Bernstein, Chief of Clinic.
S. J. submitted September 29, 1935.

Recent animal experiments seem to indicate that proteins play an important role in the production and prevention of experimental ulcers. Hoelzel and Da Costa (2) and Weech and Paige (3) have shown that a deficiency of protein in animal diets results in gastric ulcer formation. In our own experimental investigations (4) we have shown that supplementary protein feedings in animals prevented experimental "pepsin-hydrochloric acid" gastric ulcers.

CLINICAL STUDY

On the basis of the above considerations we began the administration of a high protein diet to patients with peptic ulcer and studied the effect upon the behavior of the disease.

A group of forty patients with a clinical history and roentgen-ray corroboration of peptic ulcer was

selected from our gastro-intestinal clinic. The average duration of symptoms with remissions, was eight years and varied from one to thirty-one years. Three of the group received no previous treatment, whereas the others had been on an alkali-diet regimen on more than one occasion. The patients were given a bland, high caloric, and high protein diet consisting of approximately 150 grams of protein, 100 grams of fat and 200 grams of carbohydrate. The proteins were given in the form of lean boiled meat, chicken, cottage cheese, milk and unflavored gelatin U. S. P.*

Gelatin was selected as the added protein because of its availability, relatively low cost, non-toxicity, and the ease with which it lends itself to frequent administration. The gelatin was supplied in blank envelopes, each containing eight grams, and was to be taken hourly, between feedings, in one-quarter glass of water for seven doses daily. The amount of eight grams was given, more for convenience, since it is the regular commercial size, than for any other arbitrary reason. Most patients tolerated the gelatin well, while some disliked the taste but made no other complaints.

All patients were ambulatory throughout the study and were seen weekly at the clinic for follow-up care. These patients were observed for a period of one year and throughout this study no medication, except occasional cathartics, was given.

The patients were questioned at each clinic visit in regard to change of symptoms, particularly relief from pain. The results have been classified in three groups. The first consisted of twenty-eight patients who had immediate relief of all symptoms. Most of this group stated that under this regimen they felt much better than with the alkali-diet treatment which they had had during previous relapses. The second group consisted of eight patients who had "fair" results. In this group the high protein diet with frequent feedings gave them no better nor worse results than the alkali-diet regimen. The third group of four patients had no improvement. The records of these patients show that at no time had their symptoms been controlled either by alkalis or foreign protein injections. The continued use of the high protein diet by the patients who were improved was stressed and but few recurrences were noted throughout the year.

X-ray studies on these patients showed a disappearance of the original niche in many instances. In others we observed slight or no change in deformities. In accord with other investigators we found that the objective findings on the roentgenograms did not always parallel the symptomatic relief.

Gastric analyses on some of these patients, using the double histamine test and gelatin, showed that there was a long period of binding of both free hydrochloric acid and pepsin. Work along these lines is being continued and will be published in a subsequent paper.

Table I shows the immediate results in patients on a high protein diet when compared with results of diet-alkali treatment.

DISCUSSION

It has often been stated, that patients with peptic ulcer can be fed almost anything, and a certain number will respond favorably. Spontaneous alleviation of symptoms in peptic ulcer patients extending over a long period has been reported by Emery and

Monroe (5) in as many as forty per cent. It is, however, striking that in our group of forty patients about ninety per cent were symptomatically improved and remained so for a long period. This is higher than their group of spontaneous remissions. The mechanism of this favorable effect is not clear. Several possibilities suggest themselves. It is possible that in our group, because of the high caloric diet, the patients gained weight and overcame any tendency to under-

TABLE I

	With High Protein Diet		With Diet-Alkali Treatment	
	Number	Per Cent	Number	Per Cent
Number of patients	40		37	
Symptom free	28	70.0	13	35.13
Moderate improvement	8	20.0	11	29.73
Unimproved	4	10.0	13	35.13
Total improved	36	90.0	24	64.9

nutrition. A high protein diet may increase the formation of bile salts (6) which in turn may relieve symptoms in certain patients (7). The frequent feedings of protein which in this study was gelatin, apparently caused more prolonged neutralization of the gastric juice. It is also possible, as pointed out by Pottenger (8) that gelatin, by its hydrophilic colloid action, lessened gastric irritation by absorbing the digestive secretion of the stomach. Gelatin is a good source of glycine, which, as shown by Brand, et al (9), is a good muscle and tissue builder, and may favorably influence the healing of a peptic lesion.

SUMMARY AND CONCLUSION

1. Based on results in the production and the prevention of experimental gastric ulcer in animals, a high protein diet was used in the treatment of forty patients with peptic ulcer.

2. The high protein regimen consisted of a mixed diet with hourly feeding of gelatin between meals.

3. Symptomatic relief was noted in ninety per cent of patients studied.

4. The theoretical considerations for the use of high protein diets are presented.

5. We feel that this method, though not considered as a specific, has a definite place in the management of peptic ulcer, especially so in cases that do not respond to drug therapy.

The Value of Gastroscopy in the Diagnosis of Phytobezoar: Case Report

By

JULIAN M. RUFFIN, M.D.

and

ROBERT J. REEVES, M.D.*

DURHAM, NORTH CAROLINA

PHYTOBEZOAR (food-ball), while not common, occurs frequently enough to justify its consideration in the differential diagnosis of obscure gastrointestinal conditions. There is no characteristic symptomatology. It may simulate ulcer, gall bladder disease, or gastric carcinoma. In general, epigastric

pain can be carried out with relatively little discomfort or danger to the patient. The first case of phytobezoar to be visualized through the gastroscope was described in 1936 by Moersch and Walter (8). The case reported in this article is, so far as can be determined, the second to be diagnosed by gastroscope.

CASE REPORT

W. T. H. (History No. 97618). A 52 year old white travelling salesman entered Duke Hospital on February 18, 1938, giving a history of epigastric distress over a period of two years. The onset of his illness was gradual. He first complained of gas and fullness in the upper abdomen with a dull aching pain in the epigastrium, coming on at any time and not related to meals or re-

Fig. 1. X-ray showing an indefinite irregularity along the lesser curvature.

pain is an outstanding feature, and hemorrhage may occur (1).

A characteristic filling defect is frequently seen by X-ray (2, 3, 1, 5, 6, 7), and the correct diagnosis is usually made before operation. However, if the mass is small and the patient a large, heavy-set individual with a stomach high up under the diaphragm, the diagnosis by X-ray is rendered more difficult and sometimes impossible.

Direct inspection of the interior of the stomach is obviously of the greatest value in such cases, and by

Fig. 2. Artist's drawing of the mass as seen through the gastroscope. A—Mass apparently attached to the wall of the stomach. B—Mass in the pyloric canal.

means of the Wolf-Schindler flexible gastroscope this

Submitted May 21, 1938.

Fig. 3. X-ray showing filling defect near the pylorus.

lied by food. He soon began vomiting with each attack, which afforded immediate relief, but the attacks increased in severity. On one occasion, one week before admission, he vomited a small amount of dark blood and later had a tarry stool. He had lost about forty pounds since the onset of his illness.

The routine examination was entirely negative except for a moderate enlargement of his heart and hypertension, his blood pressure being 190/120. The abdomen itself showed nothing of interest.

There was a slight secondary anemia; the hemoglobin

Fig. 4. Photograph of specimen.

was 72% (11.2 grams), and the red count 4,200,000. The Wassermann reaction was negative. Stool examination showed a 4-plus Benzidine. Urinalysis was negative. A tentative diagnosis of carcinoma of the stomach was made.

Gastro-intestinal X-ray examination, on February 24, showed a 30% gastric residue and an indefinite irregularity along the lesser curvature (Fig. 1). There was no filling defect. Gastric analysis revealed 60 degrees of free HCl. The stomach contained a large amount of gas.

Gastroscopy: On February 25, a Wolf-Schindler flexible gastroscope was passed and the interior of the stomach examined. A large black mass (Fig. 2A) was seen which was smooth and glistening and apparently 3 to 5 cm. in diameter. It seemed to be attached to the posterior wall and did not move on rotating the patient. Gastroscopy was repeated 5 days later, and the mass was observed in the pyloric canal (Fig. 2B).

On March 3, the gastro-intestinal X-ray series was repeated. There was no evidence of ulcer though a filling defect, not seen in the first examination, was observed near the pylorus (Fig. 3).

Operation: On March 7, under spinal anaesthesia, Dr. George Joyner removed the foreign body with ease. The patient had an uneventful convalescence and has been entirely symptom-free since the operation.

Pathological Report (Dr. Phillip Parsons). Gross appearance: The specimen (Fig. 4) measured roughly 9x4x3 cm. It was very black on the surface, but the inside was a light brown and granular. Microscopic section: Vegetable matter with many fat cells.

Chemical analysis (Dr. Haywood Taylor). This material gives no test with the usual protein reagents. There is a small amount of fatty material, and it is partially soluble in the usual cellulose solvents. It gives a good test

for lignin, and apparently the material is of a woody substance.

DISCUSSION

The development of a food-ball in the stomach is frequently associated with the ingestion of persimmons. This patient stated that he eats at least a quart of persimmons every fall, and has done so for the past thirty to forty years.

While the diagnosis can usually be made by X-ray, still there are cases in which no filling defect can be detected even after a most careful examination. In such cases, the diagnosis could be made readily by gastroscopy.

SUMMARY

A case of phytobezoar, in which the diagnosis was made by gastroscopy and confirmed by operation, is reported. The importance of gastroscopy as a diagnostic procedure in obscure gastro-intestinal conditions is emphasized.

Ulcerative Colitis of 28 Years' Duration With Recovery

By

WILLIAM Z. FRADKIN, M.D.
BROOKLYN, NEW YORK

THE purpose of this paper is to present a case of ulcerative colitis which was etiologically undiagnosed for 28 years. Because of the long duration of the illness, the nature of the infection, its many interesting manifestations and the complete recovery, the case is worthy of record.

*From the Department of Medicine, Division of Gastro-Enterology, and the Department of Laboratories, Division of Bacteriology, Jewish Hospital of Brooklyn.
The author is indebted to Dr. Milton G. Wasch for the complete review of the X-ray films.
Submitted April 27, 1936.

REPORT OF CASE

History: On May 12, 1930, M. F., white male, age 50 years, was admitted to the gastro-intestinal clinic of the Jewish Hospital of Brooklyn, complaining of a bloody diarrhea of 23 years' duration. He gave the following history:

In January, 1907, a few weeks after his marriage at the age of 27, he was stricken with a bloody diarrhea associated with severe pains in the lower abdomen and sacral region. He was admitted to a hospital where his blood,

Fig. 1. 1931. Opaque enema study. Spastic cecum, transverse and descending arms. Complete loss of normal haustration. Coarse irregular peristalsis, finer movements of colon lost. Incompetent ileocecal valve with considerable of the clysmia in the ileal coils.

urine and stools were examined but nothing of significance was found. After eight days he was discharged with less abdominal pain though the diarrhea continued. Private physicians were consulted who repeated stool examinations, but no causative agent was discovered. X-ray studies showed the disease to be a colitis. Countless medicaments were prescribed but without benefit. The patient learned by experience that castor oil controlled the bowel discharges for as long as one week. In later years however, even this remedy did not control the diarrhea. The rectal discharges were often so spontaneous that the distance from the adjoining room to the bathroom required too much time to cover without soiling his clothes. The use of specially tailored water-proof trousers enabled him to keep his business appointments. Five years after the onset of the illness, at the age of 32, the patient developed a generalized eczema over the entire body, a bilateral eczematous blepharitis, and sycosis barbae of the chin. This skin condition continued for 23 years and only disappeared for short periods of time about every two or three years in spite of all types of medication. In 1914 a hemorrhoidectomy was performed at Bellevue Hospital. The operative site apparently healed well and the patient thought that he had less blood in the stools following the operation. In the winter of 1929 he lost all his hair due to a vesicular and pustular eruption of the scalp. Towards the end of the winter as the lesions healed his hair grew back. On the advice of physicians he had all his teeth extracted in order to remove all possible foci of infection.

The remaining history was of no importance. The patient was always well and could not account for the source of the infection. He was married. His wife was living and well. She gave birth to six children during her husband's chronic ailment and all are well. No one in the family ever suffered with diarrhea. The family history was irrelevant.

The patient was treated at the gastro-intestinal clinic

for a period of 15 months. Diagnoses were made at various times of chronic nonspecific ulcerative colitis, achylia gastrica, pancreatic dysfunction, fermentative dyspepsia, and emotional diarrhea. Therapy for these conditions was ineffective.

First Admission: On August 19, 1931, the patient was admitted to the In-patient department for further study. His temperature, pulse and respirations were normal. He was emaciated but well oriented and cooperative. His hearing was somewhat impaired. The positive findings were mainly those of generalized eczema, chronic eczematous bilateral blepharo-conjunctivitis, sycosis barbae, hypertrophied tonsils, toothless gums, postnasal drip, emphysema of chest, marked left lower quadrant tenderness, and right inguinal hernia. A gastro-intestinal roentgen study in the clinic on March 17 and again in the In-patient department on August 22 produced similar plates (Fig. 1). The large bowel emptied in 24 hours indicative of hyper-peristalsis. There was complete loss of haustrations and a marked irregularity of its lumen indicating an advanced stage of colitis. The enema passed through an incompetent ileo-cecal valve. The entire colon from rectum to cecum took part in the pathological process. (Stool examinations were done on the same days with the barium X-rays and therefore invalidated the stool studies). The proctoscopic examination revealed an edematous, reddened, diffusely ulcerated mucous membrane not characteristic of a specific infection.

Laboratory Studies: Examination of the blood revealed a hemoglobin of 70%, red blood cells 4,130,000, white blood cells 6,800 with polymorphonuclear cells 67%, lymphocytes 28%, eosinophiles 2%, mononuclears 3%, Wassermann and Kahn tests negative; blood sugar 105 mg., urea nitrogen 9 mg., creatinine 1.6 mg. The urine analysis was normal. Repeated stool examinations were negative for ova or parasites. Gastric analysis revealed a free hydrochloric acid of 12 and a total acidity of 20. Duodenal aspiration showed an occasional white blood cell and epi-

Fig. 2. 1932. Colitis apparently controlled with restitution of normal markings throughout. Note normal cecum and the well defined regular haustrations of the transverse and descending arms.

thelial cell, and was sterile on culture. There was no trypsin or amylase present. Basal metabolic rate was -6%.

The patient was discharged with the diagnosis of chronic nonspecific ulcerative colitis and referred to the

Fig. 3. 1934. Coarse peristalsis with loss of normal haustration again present (see Fig. 1) recurrence of colitis.

Out-patient department for further care. A colon study on July 19, 1932 (Fig. 2) revealed marked anatomical improvement even though the patient still complained of diarrhea. The haustrations returned and were well marked and regular. The smooth rigid tubal outline could not be seen.

The patient was treated for the generalized eczema of the body in the Dermatology clinic from the time of his admission to the Out-patient department in May, 1930. The results were discouraging with all types of internal and external medications. From May to October, 1933, he was given weekly intravenous injections of sodium iodide. Although the skin condition did not show improvement the diarrhea stopped for five months—for the first time since the onset of his illness. In view of the etiology later found the effect of the sodium iodide on the diarrhea is interesting. Iodine is an excellent amebicidal drug. Potassium iodide orally had no effect on the diarrhea.

Second Admission: It occurred to some of the clinicians that reduction of the activity of the thyroid gland might also diminish peristalsis. The patient was therefore hospitalized on June 15, 1934, and given X-ray therapy to the thyroid. Six treatments were given without the slightest benefit. On June 23, 1934, another colon study with a barium enema revealed the smooth tubal appearance of marked inflammation (Fig. 3). There were no signs of haustrations and marked narrowing and irregularity of the lumen could be seen. The picture was similar to that seen in 1931.

In July, 1934, the writer described an instrument (1)

by means of which exudate could be aspirated from the ulcers under direct vision through the sigmoidoscope. The patient was therefore called back to the clinic for further etiologic investigation by this method. On July 8, 1935, an aspirated specimen obtained from the ulcerated lesions under direct vision through the sigmoidoscope and immediately examined on a warmstage microscope revealed numerous motile amebae of the histolytica type. This solved a veritable mystery of 28 years' duration.

Third Admission: On the following day the patient was readmitted to the hospital for anti-amebic therapy. An electrocardiogram revealed myocardial damage. The cardiologist felt however that emetine hydrochloride given under close observation was not contraindicated. The drug was given intramuscularly in doses of one grain for ten days. The diarrhea stopped promptly and the patient was discharged two weeks after admission. Carbarsone, grains four, B.I.D. for ten days, then Vioform, grains four, six times daily for sixteen days were given orally in the Out-patient department with complete recovery. The patient gained 25 lbs. within nine months, and noted gradual

Fig. 4. 1938. Tubular bowel, peristaltic tone lost, lumen narrowed, haustrations missing. Atonic colon, secondary to chronic colitis. Note involvement of upper sigmoid in pathological process.

disappearance of the skin lesions. On April 30, 1936, in the clinic, sigmoidoscopic examination revealed a smooth, finely scarred granular mucosa without evidence of congestion, petechiae, or ulcerations. He was last seen at the presentation of his case to the Staff Society on January 11, 1938, feeling perfectly well. He had gained almost 70 lbs. in weight and had not suffered with the skin lesions since the specific treatment was instituted. A barium enema on this day showed a smooth, narrowed, shortened colon completely lacking haustral markings (Fig. 4).

While the patient was in the hospital an experiment was carried out which definitely and completely proved that stool examinations as done routinely in many hospitals are

thelial cell, and was sterile on culture. There was no trypsin or amylase present. Basal metabolic rate was -6%.

The patient was discharged with the diagnosis of chronic nonspecific ulcerative colitis and referred to the

Fig. 3. 1934. Coarse peristalsis with loss of normal haustration again present (see Fig. 1) recurrence of colitis.

Out-patient department for further care. A colon study on July 19, 1932 (Fig. 2) revealed marked anatomical improvement even though the patient still complained of diarrhea. The haustrations returned and were well marked and regular. The smooth rigid tubal outline could not be seen.

The patient was treated for the generalized eczema of the body in the Dermatology clinic from the time of his admission to the Out-patient department in May, 1930. The results were discouraging with all types of internal and external medications. From May to October, 1933, he was given weekly intravenous injections of sodium iodide. Although the skin condition did not show improvement the diarrhea stopped for five months—for the first time since the onset of his illness. In view of the etiology later found the effect of the sodium iodide on the diarrhea is interesting. Iodine is an excellent amebicidal drug. Potassium iodide orally had no effect on the diarrhea.

Second Admission: It occurred to some of the clinicians that reduction of the activity of the thyroid gland might also diminish peristalsis. The patient was therefore hospitalized on June 15, 1934, and given X-ray therapy to the thyroid. Six treatments were given without the slightest benefit. On June 23, 1934, another colon study with a barium enema revealed the smooth tubal appearance of marked inflammation (Fig. 3). There were no signs of haustrations and marked narrowing and irregularity of the lumen could be seen. The picture was similar to that seen in 1931.

In July, 1934, the writer described an instrument (1)

by means of which exudate could be aspirated from the ulcers under direct vision through the sigmoidoscope. The patient was therefore called back to the clinic for further etiologic investigation by this method. On July 8, 1935, an aspirated specimen obtained from the ulcerated lesions under direct vision through the sigmoidoscope and immediately examined on a warmstage microscope revealed numerous motile amebae of the histolytica type. This solved a veritable mystery of 28 years' duration.

Third Admission: On the following day the patient was readmitted to the hospital for anti-amebic therapy. An electrocardiogram revealed myocardial damage. disappearance of the skin lesions. On April 30, 1936, in the clinic, sigmoidoscopic examination revealed a smooth, finely scarred granular mucosa without evidence of congestion, petechiae, or ulcerations. He was last seen at the presentation of his case to the Staff Society on January 11, 1938, feeling perfectly well. He had gained almost 70 lbs. in weight and had not suffered with the skin lesions since the specific treatment was instituted. A barium enema on this day showed a smooth, narrowed, shortened colon completely lacking haustral markings (Fig. 4).

While the patient was in the hospital an experiment was carried out which definitely and completely proved that stool examinations as done routinely in many hospitals are

frequently misleading and embarrassing to the clinician. The following table presents the facts:

Aspirated Exudate vs Stool Specimen

	Aspirated Specimen	Stool Specimen
July 8, 1935	amebae	
July 11, 1935		negative
July 12, 1935	amebae	
July 13, 1935		negative
July 22, 1935	amebae	

COMMENT AND SUMMARY

This patient suffered with ulcerative colitis for 28 years. The etiology of the disease remained undetermined until material for examination was aspirated directly from the ulcers and immediately examined on a warmstage microscope. The routine stool examinations were unreliable and misleading. The liver, al-

though a common secondary site of amebic infection, resisted pathologic amebic invasion. The generalized eczema of the skin as well as the acute dermatitis of the scalp with temporary loss of hair may be attributed to the effect of the parasite or its toxins. It is of interest to note that the intravenous administration of sodium iodide controlled the diarrhea for a period of five months. This would suggest its use in the more protracted cases of amebiasis where the parasites have migrated to the liver and other organs and where the use of emetine is contraindicated.

This case also shows that an amebic infection of the colon may for a short period of time spontaneously regress to a state of practically normal roentgenologic findings.

Treatment of Operable Rectal Cancer in Poor Surgical Risks

By

GEORGE E. BINKLEY, M.B. (TOR.)

NEW YORK, NEW YORK

ONE of the main obstacles to routine successful treatment of operable rectal cancer is the inability of certain patients to withstand the most appropriate forms of rectal resection. This inability, which is largely determined by old age, or age associated with heart, lung, kidney, metabolic or other chronic disease, varies considerably in a miscellaneous group of patients. Due to this variation, patients may be conveniently separated, as to the possibilities of withstanding treatment, into four groups, good, medium, poor and bad surgical risks. This classification is based upon a careful history and detailed physical and laboratory investigations.

Patients who are good surgical risks may be subjected to the most radical and ideal form of rectal resection, i.e., the one-stage abdomino-perineal operation, from which the operable mortality is comparatively low. Two-stage abdomino-perineal resections are applicable to the majority of patients classified as medium surgical risks. Graded procedures are often preferable when dealing with advanced operable disease or badly infected tumors at or near the recto-sigmoidal junction. Patients classed as bad surgical risks are unsuitable for any form of radical treatment because of their very poor physical condition.

Treatment of poor surgical risks may be by irradiation or by one of the less radical forms of surgical removal. The form of surgery that is best suited for this group of cases is the perineal type of rectal resection. This operation, although not always the ideal one, as regards wide dissection and curative effect, can be performed and has a low operable mortality. It is capable, moreover, of producing a good percentage of clinical cures in the less advanced stages, and of providing a high degree of palliation in the advanced operable stages of disease. Radiation therapy, which consists of applying roentgen and radium rays to the primary tumor, is gradually increasing in popularity in this type of patient, because of the high percentage of good results. This latter method, un-

fortunately, is not suitable for routine employment in all poor surgical risks, largely because of inaccessible locations and advanced stages of disease. Both methods have a field of usefulness in this type of surgical risk. Selection of treatment can best be made by means of a working knowledge of the comparative advantages and limitations of both radiation therapy and perineal resections.

Radiation therapy is the method of choice when it offers equal or better possibilities to those afforded by resection. Treatment by the physical agents is greatly preferred by the average elderly patient; because, if successful it eliminates long periods of hospitalization and the dangers, worries and inconveniences of surgery. Moreover, in most instances the patients retain a normal or practically normal functioning rectum, since colostomy is necessary in only a relatively small percentage of cases. The reaction or strain from adequate irradiation of a small or medium sized tumor is less severe than the shock and complications that usually follow surgical removal. The reaction following irradiation of a small rectal cancer is practically nil. On the contrary, the reaction following large dosages of radon, which are necessary for large, advanced, border-line operable cancers, may be severe and prolonged for weeks. It is through careful selection of cases that severe reactions may be avoided and a high percentage of gratifying results may be obtained.

I. Rectal cancers most suitable for irradiation are the small, early, localized lesions. Such tumors must be sufficiently accessible to be approached with the protoscope so that their size, shape and degree of infiltration can be accurately estimated. Accessibility of the tumor and the surgeon's knowledge of the above factors are essential for adequate applications of radon. Medium or large sized cancers of grade I and grade II malignancy, in which the induration is clearly defined, may also be favorably influenced by the physical agents. The percentage of clinical cures

following treatment of large lesions will be somewhat less than in the case of small tumors. The problem in selecting treatment for patients with well-established disease is to determine whether the whole tumor mass can be favorably influenced and whether the irradiation reaction is likely to be more severe than the effects of surgical removal.

II. Rectal resections are reserved for the group of poor surgical risks with tumors that do not lend themselves well to radiation therapy. This group includes a fair percentage of patients with medium, advanced and large cancers. Inaccessible lesions and tumors that are poorly defined and badly infected are also candidates for resection. The majority of patients selected for surgery will be benefited by preoperative radiation therapy. This additional treatment may influence the prognosis favorably and make the resection less difficult.

RADIATION THERAPY

Radiation therapy of rectal cancer in our Clinic has consisted chiefly of external irradiation combined with interstitial implantations of gold-filtered radon seeds. A small number of cases included in this report have received local rectal applications in place of the gold seeds. In a few instances, when dealing with polypoid cancers, the electric snare has been employed to remove redundant areas of tissue in order to facilitate the adequate placement of radon seeds.

Treatment is commenced with daily, fractional, external dosage of roentgen rays. Six or seven portals of entry about the pelvis are employed. The total dosage delivered through each portal is kept within the tolerance of the skin so that permanent skin damage does not result. These treatments, which do not require hospitalization, seldom produce an untoward constitutional reaction. They are completed within two to four weeks according to the amount of both the daily and the total dosage administered to each portal.

Interstitial irradiation, which has been employed in the majority of our cases, consists of implanting gold-filtered radon seeds into the tumor mass ten to fourteen days after completion of external therapy. The dosage of buried radon must be sufficient to devitalize all the malignant cells, and, depending upon the size of the tumor, varies from 1000 to 5000 millicurie hours. The radon seeds are inserted by means of long trocar needles, and are placed in position by direct vision through a well-lighted proctoscope. Anesthesia for implantation is seldom required, and patients remain in the hospital only a few days.

Surface applications of radium, with employment of the fractional dosage technique, have been used in a small number of cases in place of gold seed implantations. The rectal applicators required for this type of treatment are fashioned after the ordinary proctoscope and placed in position by direct vision. They are constructed so as to protect the normal rectal mucosa with an additional lead filter whose thickness corresponds to one-half the diameter of the applicators. Daily dosages varying from 100 to 250 millicurie hours have been administered at 0.75 to 1.2 centimeters from the surface of the tumor. Daily treatments are continued for periods varying from three to six weeks with a total dosage of 2000 to 5000 millicurie hours. Although this type of surface irradiation by the fractional method is still in the experimental stage,

the results so far obtained suggest the continuation of its employment in certain types of rectal and anal cancer.

Supplementation of the physical agents by colostomy, or snare removal of redundant areas of tumor, is sometimes advisable. In a few cases, redundant areas of low grade cancer which protrude into the lumen and interfere with radon applications, are removed with the electric snare, after completion of external treatment. Anesthesia is seldom required for this minor operation and patients are confined to hospital for only one or two days. Colostomy is no longer routinely employed with irradiation of rectal cancer. Comparatively few operable cases, treated in this manner, are benefited to any great degree by short-circuiting the fecal stream. An artificial anus is reserved for a few advanced border-line cases, when obstructive symptoms are troublesome, and for a few patients in whom an abdominal opening facilitates the implantation of radon.

SURGERY

Perineal resections, which are well withstood by the majority of poor risks, are routinely employed for cases which are unsuitable for radiation therapy alone. Occasionally, with a high-lying tumor, a graded abdomino-perineal operation is advisable. In the majority of our cases, perineal resection has been preceded by an abdominal colostomy. An artificial anus on the abdomen is more easily cared for than one in the perineal region. Moreover, such an opening often permits a wider dissection. Very obese patients, in whom the construction of a colostomy is a major operation, and those who refuse to submit to such a procedure, are operated upon without preliminary colostomy. Dissection in all cases should be wide, with removal of as large a section of the rectum and as much of the adjacent tissues as is possible. Wide resections are withstood as well as those of a limited nature, and offer greater possibilities of permanent clinical cure.

Operative fatalities in poor surgical risks can be reduced to a minimum by careful preoperative preparation and detailed postoperative care. The former consists in eliminating intestinal intoxication and of improving the general condition by the use of saline cathartics, selected diets, liver extract, tonics, etc. The benefit of such treatment is readily manifest by an increase in appetite, feeling of well-being, etc. Practically all of our poor risks receive preoperative external irradiation. The period required for external therapy affords an excellent opportunity for close observation of the case, and permits the employment of the above measures to good advantage.

The benefit derived from blood transfusions in poor surgical risks can scarcely be over-estimated. All patients receive one or more transfusions before operation and a number have received as many as three during early convalescence. A liberal supply of blood appears to prevent or lessen the severity of shock and the many complications frequently encountered following radical operations. In all probability, more poor risks die of complications than from the shock of the operation itself. Careful nursing is also essential. The liberal use of hypodermoclysis, intravenous injections of saline and glucose, together with administration of digitalis in certain cases of

cardiovascular disease, appears to have helped greatly in preventing postoperative fatalities.

RESULTS

Results following the above forms of treatment in poor surgical risks are encouraging. From 1931 to 1935 inclusive, 39 of the patients treated in our clinic were classified as poor surgical risks. There were 17 male and 22 female patients. 22 were treated by radiation therapy and 17 subjected to perineal resection.

Of the 17 patients surgically treated, 15 had abdominal colostomies and 2, perineal resections without preliminary colostomy. Convalescence was stormy in 8 instances, with one postoperative death. Six patients that survived the operation died of cancer. The length of life varied from six months to three years and eight months. Of the 10 remaining, 9 are well and considered clinically free of disease for periods varying from one and one-half to four and one-half years. The tenth patient is still alive, four and one-half years after treatment, but has a large liver and symptoms suggesting metastatic disease.

22 patients were selected for radiation therapy. Colostomies were constructed in two instances. Redundant areas of tumor tissue were removed with the electric snare to facilitate radon applications in six cases. Results to date in these 22 patients may be summarized as follows: one—poor, four—medium and 17 good results. The poor result occurred in a man who lived but eight months; the cause of death is un-

known, but is thought to be due to disease or to over-treatment. Medium results were obtained in two patients who died with disease three years and ten months, and four years respectively, after treatment. The two other patients are living. One female was free of disease for more than four years, but recently developed a recurrence. The other, a male, has disease two and one-half years after treatment.

Of the 17 good results, to date, one patient died of coronary thrombosis without any evidence of cancer two years and eight months after treatment. The remaining 16 patients are alive and considered clinically free of disease, 5 of whom have passed the four and one-half year period. The periods of freedom from disease of the remaining 11 patients vary from one and one-half to four years.

CONCLUSIONS

Early diagnosis is the greatest asset to successful treatment of rectal cancer. A fair percentage of poor surgical risks with operable disease may be successfully treated by radiation therapy, and retain a normal or practically normal functioning rectum. Cases unsuitable for radiation therapy are best treated by one of the less radical forms of rectal dissection. The choice of treatment rests with the accessibility, size and degree of infection of the primary cancer. Operable mortality may be kept comparatively low by selective surgery and by careful preoperative and post-operative care.

A Practical Method of Analyzing the Precipitating Factors Producing Peptic Ulcer

By

EDWARD J. CALLAHAN, M.D.

and

DONALD W. INGHAM, M.D.

SARATOGA SPRINGS, NEW YORK

IF one were to attempt an analysis of the various theories propounded to explain the etiologic factors responsible for peptic ulcer, he would find himself lost in a maze of conflicting ideas. The literature is self explanatory, i.e., no unanimity of opinion exists in the minds of the investigators regarding the etiologic basis of this ever increasing medical problem.

It is not the purpose of this paper to attempt to reduce the chaos to order nor to complicate the situation further by adding another theory. Rather, it is our idea to outline a practical means of office investigation by which one may determine the precipitating factors, producing a gastro-intestinal upset.

An appraisal of the most frequently mentioned etiologic factors responsible for gastro-intestinal symptoms arising from peptic ulcer will serve as an introduction to the subject of this article. These are summarized excellently by Rivers (1) into four groups: 1. Neurogenic factors. 2. Circulatory disturbances. 3. Erosion of tissue by acids. 4. Inflammation and infection. These factors working alone or

together may be responsible for the production of peptic ulcer. It seems reasonable that the interaction of all the factors may be the precipitating cause.

For over a century, the belief has been widespread among physicians that prolonged emotional activity and psychic trauma exert a powerful influence on the production and oft times prevent recovery from peptic ulcer. Cushing (2) quotes Rokitsky as being the first to teach that there was an interaction between the nervous system and the gastro-intestinal tract which under adverse conditions resulted in ulceration. Robinson (3) in a well controlled work advances his proofs in defense of the psychogenic origin or exacerbation of peptic ulcer. He believes that an imbalance in the vegetative nervous system provides the exciting unfavorable stimuli which lead to the production of peptic lesions. Although his article was criticized by Bonta (4), the fact remains that many "inquiring minds" still adhere to the theory that the nervous system is the keystone in the arch of etiologic factors.

Ivy (5), whose clinical experience is corroborated

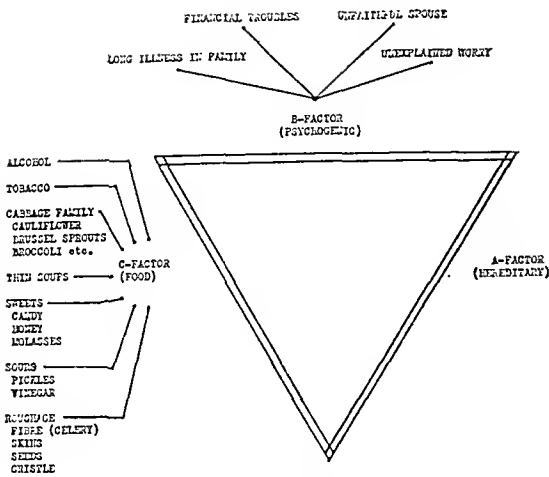

Figure 1

Fig. 1. Analytic chart.

by physiologic experimentations, realizes "the rather important role played by sustained anxiety and associated unhygienic eating habits in the genesis of peptic ulcer." The premise, that the central nervous mechanism, which is responsible for the psychic inhibition of the motility of the stomach, may be conditioned, may also be important in the analysis of the productive factors. It has been shown by reliable investigators that hyperacidity of the stomach is always present in the anxiety complex and in a patient consciously or subconsciously nervous but not afraid.

It is evident from the cursory review of the current theories that despite criticism against the neurogenic origin it is yet the most constant of them all. In a careful study of the food habits of patient with ulcer compared to normal control persons, Elder and Emery (6) were not convinced that quantitative nor qualitative food factors exerted any role in producing peptic ulcers. This well controlled work however does not detract from the value of a well arranged dietary regime in the treatment of peptic ulcer because a well arranged, non irritating, low residue diet is the foundation upon which the treatment is built.

Although studies in the heredity have not clearly demonstrated that there is a transmitted tissue susceptibility in peptic ulcer, such may be assumed because there seems to be a correlation between body build, personality, etc., and this common gastro-intestinal lesion.

A satisfactory uncomplicated procedure has been employed by us in an office practice of gastro-enterology. It provides an excellent graphic explanation of the fundamental reasons or possibilities working alone or together which are responsible for the patient's symptoms. It facilitates the psychologic examination, which, is important not only in the diagnosis, but also in the treatment of peptic ulcer.

We have constructed two charts each containing an equilateral triangle the sides of which are represented by letters A-B-C. A, representing the hereditary factor, B, the psychogenic factor and C, the food factor. The first chart (Fig. 1) represents the diagnostic or analytical chart and is constructed with the apex of the triangle downward which symbolizes im-

balance. This demonstrates to the patient the mechanism of his recurrences and recurrences by the ease with which this triangle may be thrown off balance. After a routine history and physical examination has been completed and a clinical diagnosis of peptic ulcer has been confirmed by fluoroscopic and X-ray examination, the first chart, (Fig. 1), is shown to the patient. It is then explained, that in our theory, the cause of peptic ulcer may be projected on the sides of the triangle. The A side of the triangle is the hereditary factor and is dismissed by explaining to the patient that he has an inherited susceptibility to peptic ulcer. The B side of the triangle or that representing the psychogenic factor, in our experience, may be divided into four main divisions as follows: 1. Long illness in the family. 2. Financial troubles. 3. Unfaithful spouse. 4. Unexplained worry, i.e., a problem which to the patient is unsurmountable and which causes continued anxiety or apprehension. The C side of the triangle represents the food factor, i.e., foods that in our estimation are harmful to a patient with peptic ulcer. Although it has been mentioned previously that the food habits of people with and those without peptic ulcer are practically the same, we feel that the third side of the triangle is necessary to complete our hypothesis.

After this survey has been made with the patient, we then return to the B side or the psychogenic factor. Here, enough time is taken to elicit and identify with one or more of the four subdivisions, the particular inciting agents responsible for the presenting complaint. Careful and oft times repeated questioning will, reveal the psychic stimulus which by constant repetition produces the onset of his disease or a recurrence. It is often not possible to elicit this information at the first visit, but we have found that the graphic charts have facilitated an earlier dissolution of the "reserve wall" with which the patient has surrounded himself consciously or subconsciously.

The second chart (Fig. 2) has been designated the therapeutic chart in which the triangle is constructed with the base downward representing stability. The sides of the triangle are labeled in the same manner as those of Chart 1. Thus, the one factor which is within our control is the food factor, hence it has been established as the base of the triangle. The remaining two sides or factors are explained as follows: On the assumption that there is a hereditary trend in peptic

Fig. 2. Therapeutic chart.

ulcer the patient must accept this and try to live within this limit of ability. For example, if he is 25% disabled by his disease, he must strive to live 100% of the 75% and not more.

The psychogenic side of the triangle is discussed and the patient is urged to seek possible solutions for the anxiety which he may have. If, however, the problem is of such magnitude that it cannot be dismissed with ease, he is cautioned to accept a philosophic view and do the best he can each day, be honest with himself, avoid fatigue and worry.

COMMENT

We have presented a workable office procedure for the study of the causes and the possibilities of treat-

ment in peptic ulcer. We believe that this method is a simple and satisfactory one and it is our impression that the successful treatment of an ulcer depends upon the determination of the underlying psychogenic factor. When this factor has been discovered and freely discussed with the patient then the treatment is well on its way. We found that this method has greatly supplemented the usual diet and alkalization treatment.

TESTING OF THE SECRETORY ACTIVITY OF THE GASTRIC GLANDS IN MAN BY MEANS OF HISTAMINE AND INSULIN

UNTIL recently all test-meals used for determining the composition of human gastric juice and for studying the course of its secretion had a common defect, namely, that one could never obtain a pure gastric juice with their aid. The juice was always contaminated with the food substances employed in the test, and with saliva and duodenal juices, or it was diluted with the solutions of those special substances (e.g. alcohol, caffeine, etc.) which were introduced into the stomach for the purpose of stimulating gastric secretion. In an article published in this Journal (Vol. 4, p. 392, August, 1937) Wilhelmj fully discussed the difference between the *gastric contents* and the *gastric secretion* and pointed out that it is a mistake to draw conclusions from the former with regard to the acidity values of the latter. However, there were further disadvantages attending the use of these test-meals, the chief being that in a diluted and contaminated gastric juice no direct determinations could be made of its acidity, or its enzymatic power, or of the concentration of its organic and inorganic components and of its mucus content.

The introduction into clinical practice of the *histamine gastric test* has made it possible to study the course of secretion and the composition of practically pure gastric juice in human subjects. It is sufficient to remember how many patients, diagnosed as cases of "achylia gastrica" on the basis of the results obtained with ordinary test meals, have shown themselves able to respond with a secretion of gastric juice to histamine. As a test of the secretory function of the gastric glands, however, histamine has its limitations. It has been demonstrated repeatedly in animals and man that histamine stimulates particularly the parietal cells of the gastric glands, and moreover in appropriate concentrations inhibits the activity of the peptic cells. (For literature, etc., see my article in this Journal, Vol. 5, p. 107, April, 1938). Gastric juice obtained through histamine administration in experimental animals possesses very high acidity, a very high concentration of total chloride and extremely low peptic power, as well as a low con-

tent of visible mucus. In man the histamine gastric juice has also a very high acidity, but the concentration of pepsin in it varies from one case to another and determinations of the enzymatic power of this type of juice do not furnish reliable data concerning the function of the peptic cells of the gastric glands. Therefore, being one of the strongest stimulants of the parietal cells, histamine may be used with great advantage in medical practice whenever it is desirable to determine the ability of the stomach to produce hydrochloric acid. No correct information concerning other components of the gastric secretion (pepsin, dissolved mucin, visible mucus) could be obtained from analysis of samples of this juice. Thus the hopes of the clinicians that with the histamine test reliable information concerning the function of the gastric glands in man could be obtained were not fulfilled.

Fortunately we possess another substance, namely, insulin, subcutaneous or intravenous administration of which provokes a copious secretion of gastric juice in animals and man. (For literature, etc., see my article on "The triple mechanism of the chemical phase of gastric secretion," appearing in the October number of this Journal). The composition of the gastric juice obtained with insulin differs from that of the juice elicited by histamine. The acidity of the insulin juice is only a little lower than that of the histamine juice, and the concentration of the total chloride is as high in the former as in the latter. But in addition the insulin juice possesses strong peptic power and contains a fairly large amount of visible mucus. In other words, insulin stimulates not only the parietal cells, as histamine does, but also other secretory elements of the gastric mucosa, namely, the peptic cells, the chief cells of the neck and the surface epithelium cells. This fact indicates that with insulin a different mechanism is involved in stimulating the secretory apparatus of the stomach than in the case of histamine. And indeed it has been proved that insulin, by producing hyperglycaemia, stimulates the vagal gastric secretory centres in the brain; the impulses from the brain are transmitted along the vagi to all those secretory elements of the gastric mucosa which they innervate. Section of the vagi or administration of atropine prevents insulin from exerting its secre-

tory effect on the gastric glands. Histamine, on the other hand, acts directly on the parietal cells, which is evident from the fact that the secretory effect of histamine is not at all, or only partly, inhibited by atropine (Gray, *Am. J. Physiol.*, Vol. 120, p. 657, 1937).

The extraordinary importance of the fact that insulin stimulates the gastric glands through the parasympathetic nervous system moved us to obtain first-hand information concerning its secretory effect. Dr. D. R. Webster in our laboratory studied this problem on a dog with esophagotomy and a gastric fistula before and after double intra-thoracic vagotomy. Five units of insulin (Connaught Laboratories, Toronto), injected intravenously, were used to stimulate gastric secretion. Before vagotomy had been performed, the secretion started about 35 to 40 minutes after the administration of insulin. By this time the blood-sugar level usually had fallen to 68-66 mg. per cent. If the blood sugar fell below 50 mg. per cent, a 20 per cent solution of glucose (150 cc.) was introduced intravenously. The gastric juice obtained by means of insulin injection in all respects resembled a typical vagal juice (e.g. that obtained by sham-feeding). It possessed high free and total acidity and strong peptic power. The effect of insulin was easily arrested by a small dose (2 mg.) of atropine sulphate. After vagotomy, as several experiments revealed, insulin was absolutely ineffective in spite of the great reduction of the blood sugar which accompanied it. On the other hand, histamine produced its usual secretory effect (see table below).

Gastric Secretion	Before Vagotomy March 3 5 units insulin	After Vagotomy (performed April 8)	
		April 29 5 units insulin	May 3 0.5 mg. histamine
Total volume (cc.)	103	129	2.7
Duration (hours)	2½	1½	3¼
Free HCl (m.eq./l.)	130	139	53
Total HCl (m.eq./l.)	141	146	107
Pepsin (Mett units)	217	0.4	27
Lowest blood-sugar concentration (mg. %)	52	—	50

On the basis of the physiological data presented above we may evaluate correctly the special importance of various gastric test-meals and select an appropriate one for a definite clinical purpose.

(1) It is advisable to use histamine in cases where it is desired to ascertain whether the stomach of a patient is able to secrete hydrochloric acid, and if so in what amount, for example in suspected cases of achylia gastrica or cancer.

(2) The insulin test may be employed whenever it is necessary to determine the magnitude of the first, or vagal, phase of gastric secretion. The ordinary test-meals (tea and bread, oat-meal gruel, etc.) usually consumed by the patient with no great pleasure cannot supply the necessary data. Yet it may be very desirable in the case of peptic ulcer or a contemplated operation on the stomach or duodenum to find out whether there is, or is not, any hypersensitivity of the vagal secretory apparatus. An excellent description of

the application of insulin to the study of gastric secretion in man may be found in a paper by Welin and Frisk (*Acta Med. Scandinavica*, Vol. 90, p. 543, 1936). The work of the Swedish investigators is the more valuable since they employed a double gastro-duodenal tube and by continuous suction of the duodenal contents prevented their contaminating the gastric juice.

(3) The histamine and insulin tests for gastric secretion may be relied on to furnish the clinician with all necessary information as to the functional state of the gastric glands. If continuous suction is applied to the gastric contents, as has been done by Welin and Frisk, the course of the secretion and the volume of the gastric juice can be easily determined. Incidentally the continuous suction of the gastric juice will prevent the possible irritation of the gastric or duodenal mucosa with undiluted gastric juice in the presence of peptic ulcer. However, the histamine and insulin tests do not give any information concerning the motility of the stomach. The ordinary test-meal (e.g. oat-meal gruel), by which the time of evacuation from the stomach can be determined, serves well for this purpose, especially if it is rendered opaque so that its passage to the duodenum may be watched on an X-ray screen.

If more detailed particulars are required concerning the course of the secretion of hydrochloric acid by the stomach and its partial neutralization by the duodenal juices, a special test-meal, e.g., 2 per cent Liebig's extract, as advocated by Wilhelmj *et al* (see the review by Wilhelmj, Finegan and Hill in this Journal, Vol. 4, p. 457, 1937) may be employed. However, like all test-meals where the gastric juice is mixed with the substance introduced into the stomach, Wilhelmj's test-meal has the usual defect, namely, that the investigator can never obtain a pure gastric juice in which he can determine not only the acidity but also the pepsin, the dissolved mucin and the mucus content.

It seems likely that the histamine and insulin tests of the functional ability of the gastric mucous membrane, owing to simplicity of performance and the exactness of the data which they provide, will in the future replace other types of gastric test-meal now in use.

B. P. Babkin, Montreal.

To the Editor:

DR. W. Lloyd Adams has called my attention to a misstatement in the article by Dr. Rutherford and myself which was published in the American Journal of Digestive Diseases and Nutrition for October, 1938, entitled, "Studies on the Use of Aluminum Hydroxide Gel in the Treatment of Peptic Ulcer." The statement was made, "Also, it has been stated (6) that the secretion of acid does not return to former levels for several weeks after the discontinuance of the aluminum hydroxide" and the basis for this was attributed to an article by Einsel, I. H., Adams, W. L. and Myers, V. C. in the American Journal of Digestive Diseases and Nutrition, 1:513-516, Sept., 1934.

This is not correct. The latter authors wrote merely that, "The free acidity of the stomach is lowered after treatment with aluminum hydroxide, but returns to the initial level after the medication is discontinued."

Naturally, Dr. Rutherford and I regret exceedingly that this error should have occurred and will appreciate having this letter published in the Journal.

Edward S. Emery, Jr.

Book Reviews

The Wheel of Health: A study of a very healthy people. By G. T. Wrench, M.D. (Lond.). C. W. Daniel Company, Ltd., 40 Great Russell Street, W.C.1, London, England. 6 shillings (\$1.50 plus 12 cents postage).

THE study of disease indicates an interest in health, since the attainment of the latter is the object of the former. The author of this book throughout his earlier years aspired to approach the health problem directly by studying carefully and in detail, people who possessed unusual health. This aspiration naturally did not greatly impress those erudite gentlemen whose function it was to sanction the subject for his thesis, with the result that Wrench fell back into the groove of standardized medical pursuits during his productive years as a practitioner, but he did not forget his innate bent, and returned to it, with avidity, only recently. With a clarity of vision, never found disassociated from great sincerity, he has captured what has the appearance of being a story of the most healthy people living in the world at present—the Hunza nation. His acceptance of the Hunzas in this role is based on exhaustive enquiry, description, reference, and comparisons, which easily persuade the reader of the validity of the claim. It is shown first of all that, actually, the Hunzas do not become ill—disease is almost unknown in their valley and among their 14,000 inhabitants. Then it is proved fairly conclusively that this happy state of unique physical fitness (old men of 70 play strenuous polo and retain the characteristics of youth) is to be attributed to their diet. The latter is low in meat, but rich in dairy products, whole grain cereals, germinating seeds, fresh vegetables, abundance of freshly picked fruit and freshly fermented wine. Not too great a variety is eaten at any one time. This diet, it will be seen, is high in "protective" substances, and resembles the ideal diet of McCollum and Simmonds, although the latter did not mention wine. The limitation of varieties at any one meal is rather a new conception, save for the teaching of certain American food fadists, which has not received the sanction of the profession. This all sounds like a simple prescription, in view of the fact that the people who eat it, and because they eat it, fail to furnish any of the exhaustive catalogue of diseases which adorn the repertoire of the European and American practitioner. Not even appendicitis? No, not even a single spastic colon, and no concession to the Western luxury of "allergy." What a benighted race indeed. But, as Dr. Wrench quickly points out, it is not quite so simple as it appears. As usual there is a catch in it. Just as the reader has seized a pen to make a list of the "Hunza diet" (which might be used on himself if not his patients, and procure for him a prolongation of his mortal itinerary) a difficulty looms up. He might eat the Hunza diet but he cannot obtain it. Those fruits, vegetables, cereals and germinating seeds are intangibly different from ours because they are the products of mountain terrace farming and each edible product today has a history through its seeds—a history in Hunza of the most expert agricultural tradition, in which soil fertilization is attained by special use of special composts. It

is almost inferred that the plain love of agriculture is not unconnected with the brilliant food results long attained in this mountain nation.

What is the moral? Merely this—that if any nation could duplicate the Hunza's agricultural fine accomplishments, and then, as a body, partake of these farm products at once after removal from the soil, and in the same balance as the Hunzas do, that nation would, in a reasonable time, enjoy freedom from practically all diseases. Is the problem of health, and particularly the problem of disease really so simple as that? Naturally one would infer not, but Wrench has so carefully controlled his findings, that logically at least he is not wrong in his conclusion.

I regard this book as one of great potential importance. Even if its main thesis might be discovered somehow to be unjustifiable, it marks an acknowledged turning point in medical interest: for why ought not a great deal of attention be directed to the study of normal health and, as here, supernormal health? Again, this book indicates, as an increasing number of books do, the intrusion of the philosophy of "wholeness" into the speculative phase of the science of medicine. Not only has our emphasis been too exclusively on the negative aspect of health, but we have been unjustified in assuming that the full prescription for health was duly supported by the multifarious agencies of society. Thus to assume that the vegetables and cereals eaten by our patients would do them good was right, but to assume that these particular products would give the utmost in physical health, was unjustified without some kind of control over the agricultural agency.

"The Wheel of Health" will probably fail to create an immediate revolution in medicine, because few if any books have ever done so, and because the attainment of the Hunza ideal, like all worthwhile ideals, is full of related problems over which no definitive profession or group of thinkers can at once exert control in any considerable degree. To physicians with the hobby of farming, it should be possible at least to put some of Dr. Wrench's ideas to the practical test, even though such test must be of a limited character. Finally, this work shall not have failed in its general intent, if it succeeds in familiarizing us with the tremendous advantage, long ignored, of directing at least part of our attention to the normal and the supernormal.

Beaumont S. Cornell, Fort Wayne.

Le Diagnostic Radiologique du Cancer de l'Estomac au debut. By René A. Gutmann. (Report to International Congress of Gastro-enterology, September, 1937). Jean Vromans, Bruxelles, 1937, 133 pages.

GUTMANN is one of the best gastro-enterologists in Paris. He is a charming, well-educated man who is in charge of a large gastro-enterologic clinic. It is a delight to find someone writing on the early diagnosis of cancer of the stomach. Too often in the past writers have described the patient who is in the terminal stages of the disease. Gutmann bases his

diagnosis on serial films, since he believes that it is impossible to diagnose cancer in its earliest stages fluoroscopically. At this point many American roentgenologists would disagree with him. He believes that once a man becomes conversant with these earliest changes, there is no great difficulty in making the right diagnosis.

Gutmann recognizes three early forms of gastric cancer: first, the infiltrating form in which the principal sign is rigidity of the gastric wall; second, the ulcerating form in which the principal sign is the niche; and third, the vegetative form, in which the principal sign is the filling defect.

The infiltrating form makes itself known by a rigidity of a segment of the gastric wall which is usually somewhat depressed. At times, when both sides of the prepyloric region are infiltrated, the pylorus has a conical contour, the so-called "sugar-loaf pylorus." Occasionally the cancer shows itself as a flat, rigid area with two straight or curved slopes at the ends. The French speak of this as the "aspect encastré" or "fitted in" appearance. This form may be complicated by the addition of a niche. At times there may be little undulations which are fixed, forming the "corrugated iron pattern."

Gutmann wisely points out that a cancer can look just like an ulcer. In the earliest stages such an ulcer may appear to heal under treatment, and the patient may become symptom free for several months. Sometimes cancer grows in one sector of the wall of the ulcer. It is a joy to find Gutmann saying "Contrary to certain modern opinions, this transformation is frequent; . . . once in five times in ulcer does not heal because it is in a stage of malignant transformation."

Gutmann is not much interested in the ulcerated cancer because this so often represents a late form of the disease. He describes in detail the appearance of the plateau-like niche which he feels is characteristic of cancer. There are also what he calls "big triangular niches." Gutmann speaks also of the "meniscus sign" of Carman, which he believes important but not pathognomonic. Cancer may begin also with a niche that cannot be distinguished from that of ordinary benign ulcer. In these cases Gutmann relies for diagnostic help partly on the therapeutic test.

In differentiating benign from malignant ulcers, Gutmann relies on a number of points. Ulcers are more likely to be malignant when situated on the horizontal than on the vertical part of the stomach, and they are far more likely to be malignant on the greater curvature. Gutmann is not quite so fearful of large niches as are the men at The Mayo Clinic. "The progressive development of irregularities in the floor of the niche should make one highly suspicious of malignancy." Gutmann learns much also from the appearance of the gastric walls around the ulcer. However, there is no sign which is absolutely pathognomonic. The hypermotility of hypomotility or hypertonicity or hypotonicity of the gastric wall is not of value in diagnosis.

In his therapeutic tests Gutmann uses intravenous proteinotherapy, and if the lesion is benign, he expects to see a rapid reduction in the size of the niche. Its persistence is a suspicious sign, and any increase in size indicates the presence of cancer. Diminution in the size of the niche will reassure, but it is not positive proof of the benign nature of the lesion. The disappearance or the approach to disappearance of the niche is the best criterion of the benignness of the

lesion. Gutmann doubts if the niche of a really malignant ulcer ever disappears.

With the proliferating type of cancer the earliest changes result in an irregular outline of the pyloric canal, or slight peculiarities in the contour of the lesser curvature, or irregular, thickened, interrupted, or "embossed" shadows of the rugae. One must distinguish if possible between benign tumors and poly-poid gastritis. Some of the early cancers closely resemble benign tumors radiologically. Benign tumors can also become cancerous.

The little volume is well illustrated, and it has summaries in English, German, Spanish and Italian.

"German for Students of Medicine and Science."

By W. F. Mainland, of the Department of German, King's College, London. Price 8 Shillings. Pp. xlvii and 160. London: Oliver and Boyd, 1938.

THIS book is designed for the use of those who, having an elementary knowledge of German, wish to increase their ability to read German scientific literature. It is neither a formal grammar nor a beginner's manual.

In the introductory section the author presents some notes on grammar and suggestions on reading. This portion of the book suffers a little from enforced brevity and an effort to cover linguistic problems that range from possible confusion of "Aus" and "Auf" to the complexities of sentence structure. There is, however, much useful information condensed into these few pages.

The main portion of the work is devoted to short and graduated selections for reading. These are suitable for class work or self-instruction. Numerous footnotes serve as a guide to grammatical construction and idiomatic usages. Many of the selections possess definite literary and linguistic interest but one may offer the criticism that insufficient effort seems to have been made to include passages from current technical journals in order to afford training in scientific terminology and word frequency. The final section is devoted to a large and complete vocabulary which makes it possible to use the book without resorting to a separate dictionary.

This volume is well planned and its material well presented. It possesses definite instructional value and should be of great assistance to those seeking a means of "brushing up" in their German. This assistance, however, is of a general nature. In the opinion of the reviewer, the book does not offer as much guidance as its title implies to those wishing to familiarize themselves with technical medical German.

Henry J. Tumen.

A B C of the Vitamins. A survey in charts. By Jennie Gregory, Baltimore, The Williams and Wilkins Company, 1938, 93 pages.

THIS little book presents in an attractive way much information in regard to the accessory factors of the diet. The material is presented in the form of drawings, diagrams and charts. There are also a few maps showing the distribution over the world of the principal centers where the several avitaminoses are commonly met. There are a number of charts showing the synthesis of the several vitamins.

This is a useful book to have around a dietitian's office where patients and students are being taught.

THE AMERICAN COLLEGE OF PHYSICIANS WILL MEET IN NEW ORLEANS, LA., MARCH 27-31, 1939

The Twenty-Third Annual Session of the American College of Physicians will be held in New Orleans, with general headquarters at the Municipal Auditorium, March 27-31, 1939.

Dr. William J. Kerr of San Francisco, is President of the College and will have charge of the program of general scientific sessions. Dr. John H. Musser of New Orleans, has been appointed General Chairman of the Session, and will be in charge of the program of clinics and demonstrations in the hospitals and medical schools and of the program of round table discussions to be conducted at the headquarters.

BARTELS, ELMER C.

Liver Function in Hyperthyroidism as Determined by the Hippuric Acid Test. Ann. Int. Med., Vol. 12, No. 5, pp. 652-674, Nov., 1938.

The clinical observations and study of the structural changes in the liver in cases of hyperthyroidism have been referred to in the literature for some time. The number of different hepatic function tests have corroborated the impression that there are varying degrees of liver impairment in thyroid disease. With all this evidence at hand to show the increasing importance of the liver in hyperthyroidism a study was planned to investigate this subject by a new method.

The liver function was determined by the hippuric acid excretion test suggested by Quick. When a normal individual takes 6 gms. Sodium Benzoate by mouth 3 gms. of hippuric acid are excreted in the urine in 4 hours.

This study is based on the results of liver function determinations in 148 cases of clinical hyperthyroidism, all of which came to operation. 78 cases had primary hyperthyroidism permitting a subtotal thyroidectomy, 39 had primary hyperthyroidism requiring a two-stage operation, and 31 cases had adenomatous goiter with hyperthyroidism permitting a subtotal thyroidectomy. Liver function determinations were obtained periodically as follows: On the day after admission; on the day prior to operation (8 to 14 days being taken for preoperative treatment); and on the 6th or 7th day postoperatively. The cases requiring a two-stage operation had determinations prior to the

second stage (six weeks usually elapsing between operations) and on the sixth or seventh day post-operatively. All cases did not have the entire series of tests. Determinations were obtained in 12 cases three months postoperatively when they returned for their usual three months metabolic check-up.

Bartels concludes that there is a reduction in the liver function as

shown by the hippuric acid test in a high proportion of cases of hyperthyroidism, only 18 cases out of 148 having a normal response to the test. The degree of change in the liver function was in direct relation to the severity, but not to the duration of the hyperthyroidism. Improvement of the liver function occurred during preoperative treatment and three months postoperatively in cases with

SNELL, ALBERT M.

The Treatment of Liver Disease.
Ann. Int. Med., Vol. 12, No. 5,
pp. 592-608, Nov., 1938.

The essential requirements in the

treatment of parenchymatous hepatic disease appear to be the maintenance of optimal conditions to allow for the regeneration and repair of the parenchyma of the liver.

The observation that a high carbohydrate diet has a definite, specific, protective effect in a variety of experimental hepatic lesions has been substantiated many times. Difficulties in the absorption, storage and utilization of vitamins may also be an element of great importance in the progression of hepatic disease, and their administration by injection has been recommended. The protective effect of Xanthine and Sodium-Xanthine on the liver is noted.

Patients having pancreatic atrophy and presumably a fatty liver were aided by the administration of the hormone "Lipocaic"; notably by the disappearance of ascites and edema and a reduction in the size of the liver.

Although complete proof of the hypothesis is lacking it is justifiable, tentatively, to assume that the syndrome of "hepatic insufficiency" is fundamentally dependent on the failure of the mechanism of detoxification. The management of hepatic insufficiency depends, primarily, on the maintenance of an adequate quantity of carbohydrates, the administration of a sufficient quantity of fluid to dilute and eliminate toxins and the correction of hypoglycemia, anoxemia or hemoconcentration, if these happen to be features of the cases under consideration.

Glucose and chlorides are best given intravenously, and the anoxemia and concentration of hemoglobin at a normal level are assisted materially by repeated small transfusions.

The disturbances between the hydrastatic pressure in the portal-venous system and the colloidal osmotic pressure of the serum, plus some injury to serosal surfaces, are considered the etiological factors in the production of ascites. On this basis the treatment of ascites is directed toward (1) improvement of the condition of the liver, (2) decrease of the portal-venous pressure and (3) elevation of the concentration of proteins in the plasma, thereby increasing the colloidal osmotic pressure of the serum.

Surgically, omentopexy, partial enterectomy and vena-peritoneostomy have been tried. Reinjection of ascitic fluid and relatively high dietary intake of proteins; transfusions of whole blood and plasma and the administration of solutions of acacia, intravenously, have all been of help in some cases. The intravenous administration of amino-acids, the intramuscular injection of liver, the feeding of concentrations of vitamin, have been of definite value. Diuretics should be used cautiously and if ineffectual should be discontinued.

Hemorrhage associated with liver disease may be of two distinct forms: (1) that which results from rupture of collateral circulatory channels and (2) that which is dependent on some intrinsic change in the coagulation properties of the blood. The control of the first situation is a surgical problem, and splenectomy or direct ligation of the coronary veins of the stomach has been attempted as a means of controlling the bleeding. The second situation, so-called "cholemic" bleeding associated with diseases of the liver, is attributable to a deficiency of pro-thrombin which, in turn, is attributable to failure of

America's Best-Known Baby has become a symbol of absolute dependability to thousands of mothers, the country over.

"Certainly there are others, but I *know* Gerber's. I've known them for years. Not long ago in one of the medical journals I read an article on canned strained foods based on Gerber's research. So when I tell a mother to give her baby Gerber's, there's no doubt in my mind about being right in my recommendation."

PEPTIC ULCER PAIN RELIEF

FROM U. S. P. GELATINE (KNOX)

... according to Recent Clinical Study

Frequent "concentrated" feedings of pure U.S.P. Gelatine have, in the experience of Windwer and Matzner,* given prompt symptomatic relief in 90% of a series of cases of peptic ulcer without the use of drugs or chemicals.

The advantages of this clinically tested peptic ulcer regime are, quick relief from pain, no untoward effects from cumulative, irritating drugs, freedom from alkalosis, and no undue interference with digestive functions.

Knox Gelatine is 100% pure U.S.P. Gelatine—85% protein in an easily digestible form—contains no sugar and should not be confused with factory-flavored, sugar-laden dessert powders. "Concentrated" feedings of Knox Gelatine are easily prepared in appetizing form and are well tolerated. Send for recipes.

A simple formula for the preparation of concentrated Knox Gelatine

CASE 1—FEMALE, 71

Uncomplicated gastric ulcer first demonstrated by Roentgen rays in 1934. Diet and alkalies afforded little relief. Accompanied by loss of weight. Repeated X-ray studies in 1936 and 1937 showed no improvement. She was placed on a diet-gelatin regime in November, 1937. Relief immediate. Gained weight. Roentgen studies in April, 1938 showed no demonstrable ulcer.

feedings, useful in peptic ulcer is, stir quickly one envelope (approximately 8 grams) of Knox Gelatine in $\frac{3}{4}$ of a glassful of drinking water and have patient drink quickly before it "sets" or gets lumpy.

IHRE, BENGTE.

Human Gastric Secretion. Acta Medica Scandinavica, Supplement XCV, 226 pp., Stockholm, 1938.

Ihre has made careful quanti-

tative studies of the enzymes, acidity, and total chlorides in the gastric juice of 24 normal and 76 pathological cases. For this study he emphasized the importance of a choice of method in obtaining specimens which would prevent, (1) loss of juice through the pylorus, (2) add mixture of duodenal juice due to regurgitation in the stomach and (3) add mixture of saliva. He used, therefore, two Rehfuß tubes combined in the double tube of Lagerlöf and Agren. With this tube in place he could obtain gastric and duodenal juices quantitatively separately. The juices have been fractioned in 20 minute periods, although occasionally the interval was

10 to 15 minutes. Histamine and insulin were used as stimuli for their experiment.

These studies were limited to gastric and duodenal ulcers, chronic gastritis and finally pernicious anemia.

On the whole individuals with gastric ulcers showed a normal rate of secretion, while in most of those with duodenal ulcer there was more or less marked hypersecretion. In chronic gastritis without ulcer the tendency was clearly toward hyposecretion. Higher degrees of acidity than normal were not observed and he concludes that the concept on hyperacidity lacks actual foundation. The majority of the pathological cases showed lowered acidity than normal. This is due to the great effect of the acid-reducing factors in the pathologically altered stomach. These factors are the diluting effect of increased secretion of mucus and the increase back diffusion of acid due to alteration of mucous membranes. A correlation between total chloride and acidity was noted in which when the acidity declined or disappeared the chlorides do not fall below 120 m. eq. per liter. Lower values are unquestionably due to add mixture of saliva. In insulin hypoglycemia the normal cases showed an average pepsin concentration two or three times greater than occurred during histamine stimulation.

BABKIN, B. P.

The Abnormal Functioning of the Gastric Secretory Mechanism as a Possible Factor in the Pathogenesis of Peptic Ulcer. Canadian Med. Asso. Jour., 38, n.s., pp. 421-429, 1938.

Babkin feels that under certain circumstances the process of gastric secretion may deviate from its course and conditions may arise which lead to destructive processes in the mucosa. To understand how this may occur he first reviews the physiology of gastric secretion.

Histamine is a stimulant of gastric juice; it stimulates the parietal cells specifically, highly acid, has the maximum total chloride, and is poor in pepsin and mucin or mucus. Babkin asks rhetorically whether histamine forms part of the normal mechanism of gastric secretion. He shows that histamine juice and sham-feeding juice are alike except for greater pepsin and total organic substances in the latter. He quotes Hollander as saying that the parietal cells alone are able to concentrate the chlorides as above the blood level and Miss Toby as showing that almost all the water of gastric juice is secreted by the parietal cells. In achylia gastrica the volume of juice is meagre, the

Choosing a Happy Medium . . .

EXICOL

(Oleic Acid and Bile Salts)

The most recent researches* again emphasize the marked fat-intolerance displayed by patients suffering from gall bladder disease, and the satisfactory therapeutic results on a low fat diet and bile salts. Contrary to recent advocates of high fat therapy, it is pointed out that overstimulation of the gall bladder, produced by such high fat diets is undesirable.

Exicol, containing a small quantity of fatty acid and bile salts, offers a solution to the controversial problem of biliary tract therapy. It is the most rational therapeutic agent in biliary disorders because—

1. It stimulates mild gall bladder contractions due to the fatty acid.
2. Increases bile secretion from 100 to 200% ** due to synergistic action of oleic acid and bile salts.
3. Makes high fat diets unnecessary.
4. Exicol is most effective as an aid in the treatment of chronic cholecystitis, biliary insufficiency and other non-surgical as well as post-surgical biliary tract disorders.

Constipation with Spasticity

BROUGHT UNDER CONTROL WITH MUCILOSE

(Stearns)

In order to determine the therapeutic efficacy of Mucilose in the treatment of constipation, clinical studies were conducted in a series of spastic colitis cases because in this disorder it is imperative that no substance be given which would irritate the sensitive colon.

Colon malfunction was diagnosed by a history of varying periods of constipation alternating with diarrhea, by palpable spasticity and finally by roentgenogram.

Most of the patients had obtained

only temporary relief from the use of cathartics, enemas, induced emesis, or from taking alkaline powders for reflex pyloro-spasm.

None of these cases was afforded satisfactory relief until Mucilose was used.

Mucilose provides bland, non-digestible, lubricating bulk in the colon. It is a hemicellulose (vegetable gum) prepared by a special process from the *Plantago loeflingii*. You can prescribe it in either of the two palatable forms—Mucilose Granules or Mucilose Flakes.

chloride concentration low, and the acidity nil, yet the peptic power of the juice is great. He hypotheates therefore that the parietal cells are stimulated to action by histamine or a histamine-like substance. Histamine is very abundant in the stomach walls and mucosa is also found in the gastric juice obtained by any method—sham feeding, vagal stimulation, or histamine injection—in the same concentration although the concentration of the histamine-equivalent varied with the rate of secretion. The histamine in the gastric juice is probably secreted by the mucosa rather than filtered from the blood since the

venous and arterial histamine are the same during gastric activity, while the gastric juice concentration increases. Also, the blood histamine is found mostly in the formed elements rather than in the filtrable elements. He concludes therefore that histamine is conveyed into the gastric juice in conjunction with the secretion of the acid producing cells. The action of the vagus nerve on the gastric glands is through the mediation of acetylcholine which is directly on the peptic cells. These cells liberate histamine in conjunction with other secretory products. The parietal cells are

stimulated through the mediation of histamine liberated from the peptic cells.

In normal gastric secretory processes during which histamine is liberated there are inherent possibilities of pathological disturbances which may lead to ulcer. As well as acting on the parietal cells, histamine acts on the blood vessels, especially the capillaries, causing a paralysis and increased permeability so the whole plasma can pass through leaving the capillary packed with formed elements. This sort of stasis has been observed and differs from actual standstill of the bloodstream because there is plasma exudation into tissue and clumping of blood cells in the capillaries. Diapedesis of red cells may also occur.

In prolonged stasis in the gastric mucosa the part deprived of its blood supply becomes devitalized and necrotic. When the mucosa only is affected an erosion occurs which has frequently been observed after large histamine doses or strong vagal stimulation. It is a long way from mucosal erosion to peptic ulcer, which is relatively rare compared to the frequency of erosion. But in certain areas of the stomach the thinness of the gastric mucosa, the less abundant blood supply, the more abundant nerve supply, and the greater exposure to mechanical factors favor the conversion of local circulatory disturbances into a major lesion of the gastric wall. In short histamine is not the sole cause of ulcer formation, nor does ulcer invariably begin through a disturbance of circulation in the gastric mucosa, but this is just one possible mechanism in peptic ulcer formation.

Edward E. Jemerin.

MARTIN, LAY.

Some of the Recent Biochemical Concepts of Gastric Secretion and Their Application to Clinical Medicine. Ann. Int. Med., Vol. 12, No. 5, pp. 614-623, Nov., 1938.

This paper summarizes the data in the investigation of changes in the acid-base pattern of human gastric secretion, the secretory concentration of hydrochloric acid and of the neutral chlorides; to determine, if possible, the type of cell, or cells, secreting these neutral chlorides; and to study the inorganic phosphates during various stages of secretion. The nature of the protein and non-protein portion of the gastric juice and a different method of titrating gastric secretion, with the interpretation of the significance of these data in their clinical sense, is submitted.

CONCLUSIONS AND SUMMARY

When gastric secretion stimulated by histamine begins, a fluid of chang-

In Chronic Cholecystitis

Through its intense choleretic influence, Decholin—c.p. dehydrocholic (triketo-cholanic) acid—steps up bile secretion by the liver cells as much as 200%. This intensified flow clears the biliary passages, lessens gallbladder tension, reduces absorption of toxic metabolites, improves gallbladder function, hastens recovery. To initiate cholelithiasis more quickly, many physicians begin therapy with intravenous Decholin sodium (10 cc. of the 5% solution), continuing therapy with Decholin 3¾ gr. tablets, one or two t.i.d.

Physicians are invited to send for the second edition of the comprehensive brochure "Biliary Tract Disturbances."

ing acid-base equilibrium is secreted into the normal stomach. The element common to these changes is chlorine which is always found in the gastric juice. Appropriate stimulation will cause it to be secreted into the stomach in greater concentration than in the resting juice, and any significant increase in the chlorides is accompanied by an increase in the titratable acidity. It will often be accompanied by an increase in the volume of hydrochloric acid whose concentration in the extracted juice varies inversely with that of the fixed base (neutral salts). In human gastric secretion the absence of

neutral salts has not been noted. Chloride concentration of the gastric juice equal to the total electrolytic strength of the serum has been found. In the majority of instances the former was below this level. The question of the monocellular source of the chloride secretion remains an open one.

The human gastric juice also contains a protein, gastro-globulin, which has been crystallized and is closely associated with pepsin and urease. There are one or more protein-like materials present and one or more of these have carbohydrate molecules attached. In this juice there are also

such materials as ammonia, urea, uric acid and amino acids whose concentrations in the normal and certain abnormal individuals usually fall within predictable limits.

The term, "combined acidity," is considered as incorrect and for clinical purposes the titration of gastric juice should be carried out to an end point with Töpfer's solution, approximately pH 3.8, since at this point practically all of the acid chlorides both as hydrochloric acid and protein chlorides have been determined.

It is believed that gastric analysis should not be resorted to as a routine diagnostic procedure but that it should be performed only in those cases in which information concerning the secretion is of importance.

B. B. Vincent Lyon and
C. Wilmer Wirts, Jr.

HESLOP, T. STEWART.

The Nervous Control of Gastric Secretion. An Experimental Study. British Jour. of Surgery, 25, 884-899, 1937-8.

Heslop undertook two series of studies in an attempt to determine the neurogenic factors in peptic ulcer.

In the first group (recovery experiments), using stomach tubes and either cats or dogs, a preoperative gastric analysis and histamine reaction was first obtained. One of our procedures was then performed, 1. bilateral splanchnectomy, 2. celiac ganglion excision, 3. bilateral vagotomy, 4. bilateral splanchnicotomy and vagotomy. The operations were found in no way to permanently influence the acidity of the juice or the rate of flow. Immediately after vagotomy there was a lower normal acidity, but this became normal again in a month. The histamine response remained unchanged nor was it affected by any procedure on any of the vegetative nerves. This is because the action of histamine is on the parietal cells alone. The value of histamine as a test of gastric function is therefore small.

In the second group (acute experiments), cats were mainly used; a tube was first inserted into the stomach through the duodenum and then the drops of juice were collected through a drop counter. Electrical nerve stimulation was applied at the rate of 50 impulses per second, this rate being found most effective in producing changes. The experiments lasted 6 hours or more and then the animal was sacrificed. In splanchnic nerve stimulation either above or below the diaphragm the results were the same. In 3 to 5 minutes there was a diminution in flow or even a fading out of gastric secretion. On cessation of the stimulus, the flow returned in 1 to 2 minutes. This he felt was a

NON-ALKALINE THERAPY IN GASTRIC HYPERACIDITY

The non-alkaline treatment of gastric hyperacidity with Creamalin presents many outstanding advantages. Adequate and prolonged acid-fixing power is provided; a distinct demulcent influence protects the gastric mucosa; the acidity of the gastric secretions is reduced; the acid-base balance remains undisturbed, thus the danger of alkalosis is obviated; there is no secondary acid rise; pain, pyrosis, eructation, and pylorospasm are quickly overcome and usually held in complete abeyance. Creamalin spells efficacy and safety in the treatment of gastric hyperacidity.

The beginning of another year of extensive use of Pet Milk by the medical profession

During the past year physicians prescribed more Pet Milk for the diets of infants and adults than had been prescribed in any previous year of our fifty-four years in business. Indications point to still more extensive use in 1939.

The record of last year is gratifying; the prospects for this year, pleasing—not only because of increased sales, but particularly because the general use of Irradiated Pet Milk by the medical profession is the logical result of a recognition of the extraordinary qualities of this form of milk—a recognition which has followed years of severe test and scientific appraisal in clinical studies and in private practice.

For every diet which calls for milk, there is no milk more wholesome, more safe, or more easily digested than Irradiated Pet Milk.

vasoconstrictor effect. However, there was also noted a rise in acidity above the resting level. Mucus appeared in the juice and the free acid fell while the combined acidity rose. In all experiments, on cessation of splanchnic, vagal, or celiac stimulation the free acid continued to rise for a while, as though it had to reach an equilibrium before it could be stopped. In splanchnic stimulation this was felt to be due to the parasympathetic content of the splanchnic nerves and with atropinization there was a sharp fall in acidity which further splanchnic stimulation was ineffectual in raising

again although the mucus secretion was greatly augmented. The splanchnics and the vagi are mixed nerves, the admixture occurring central to the thorax since cats with vagotomy still had enough vagal content in the splanchnics to influence the acidity.

Stimulation of the celiac ganglion did not influence the rate of flow quite as readily as when the splanchnics were stimulated and the acidity was raised to a higher degree. After atropine, the behavior was the same as in the splanchnic experiments; the acid fell and coelica ganglion stimulation was more effective in depres-

sing the flow of juice but had no effect on the acidity. This less marked effect is due to the large vagal component of the coeliac axis reaching it through the celiac branch of the posterior vagal trunk.

On vagal stimulation, after a 3 to 5 minute latent period there was an increase in flow and acidity. This was appreciably higher than on splanchnic stimulation and tended to persist after the cessation of stimulation.

In hypothalamic stimulation a Souttar machine emitting impulses at the rate of 50 per second was used. A rectangular area demarking the projection of the hypothalamus on the brain surface was marked out. Two sensitive points were found in this area, one at the anterior end, the other at the posterior. On stimulation of the anterior point, after a latent period usually of 6 minutes though sometimes as long as 15, there occurred a sustained increase in the flow of gastric juice accompanied by an increase in acidity. After stopping the stimulus, the increased flow persisted for a variable time and then relapsed. The response was very much like that on vagal stimulation. On stimulating the second, posterior, sensitive point the response was not as certain and definite as at the anterior point although when a change occurred it was always of the same nature. After 6 to 10 minutes the flow of juice slowed and stayed slow until the stimulus was stopped. There was then a slow return to the pre-stimulation level. Also there was an increase in mucus and a decrease in free acid. Here the response was a pure sympathetic one. When vagotomy was performed at the usual level anterior hypothalamic stimulation still caused an increase in the flow of secretion and the acidity though not as much as in the non-vagotomized animal, indicating that the vagi in small part reached the stomach through an alternate route. As far as the author could determine, the hypothalamus between the anterior and posterior sensitive points was silent as far as gastric secretion was concerned.

The formation and secretion of mucus, he concludes, is in part, at any rate, under nervous, (sympathetic) control.

HOLLANDER, FRANKLIN AND JEMERIN, EDWARD E.

Preparation of Stomach Pouch Without Interruption of Vagal Supply. Proc. Soc. Exp. Biol. Med., 39, 87, 1938.

In a previous publication (see preceding abstract) it was shown that both the ventral and dorsal trunks to the dog's stomach run symmetrically with one another along the lesser

to promote BILIARY DRAINAGE

SPECIFIC MEDICATION

in specific biliary
conditions

Plessner bile salt preparations present specific medication for specific lesions of the hepatobiliary tract.

TAUROCOL (Plessner)

Tauocol is of unusual therapeutic value in mild chronic cholecystitis. Containing bile salts, stomachics, and laxatives, it enhances biliary drainage and stimulates intestinal peristalsis.

TAUROCOL COMP. (Plessner)

Contains pepsin and pancreatin in addition to the ingredients of Tauocol. Indicated when gastric or intestinal indigestion complicates gallbladder disease.

Duochol (Plessner) fulfills every demand of the modern therapeutic approach in chronic cholecystitis, toxic hepatitis, stone-free cholangitis, and as an aid in the prevention of gallstones in cholelithic involvement. Its combination of highly purified bile salts with sodium salicylate increases the flow of bile from the liver, and improves gallbladder emptying, in this manner promoting biliary tree drainage with its beneficial therapeutic influence.

The reasonable price of Duochol (Plessner) makes it particularly advantageous in the many cases where prolonged administration or frequently repeated courses of therapy are required.

Generous samples of all Plessner bile products, together with literature, sent on request.

THE PAUL PLESSNER CO., DETROIT, MICH.

THE DIARY OF DR. PEPYS

Up betimes and to the office, there to find before me the Banker Castlemaine who, at the instant of my entrance, declareth himself distressed.

A pompons gentleman, much given to publick dining. He hath for three nights sat late at banqueting, which he will never forego.

I did prescribe Cal-Bis-Ma for him for the quick relief he finds in this fine powder.

... Dr. Pepys is right. When hyperacidity gives rise to gastric distress, Cal-Bis-Ma will give prompt and prolonged relief. Sodium bicarbonate and magnesium carbonate for quick action; calcium carbonate and bismuth for prolonged effect, and colloidal kaolin to adsorb the gas formed in the neutralization process. These ingredients, carefully matched for density, are held together in a colloid base that assures uniform distribution and dosage. Trial supply gladly sent to physicians.

CAL-BIS-MA

A WILLIAM R. WARNER PRODUCT
for gastric neutralization and sedation

Powder in tins of 1¼, 4 and 16 ounces; tablets in boxes of 30, bottles of 110

WILLIAM R. WARNER & CO., INC., 113 West 18th Street, New York City

curvature. Branches from the main trunks pass transversely to the long axis of the stomach. This is contrary to the concept of the vagal anatomy of the dog's stomach held by Pavlov and the Pavlov pouch which was made on this anatomical basis, therefore, lacks the bulk of its vagal supply.

A gastric pouch with uninterrupted vagal innervation was devised as follows: An incision is made through all the layers of both anterior and posterior gastric walls from a point on the greater curvature, about 1 inch proximal to the end of the pyloric antrum, to about half way across the stomach walls. This incision runs parallel to the vagal branches. From

the ends of this incision, mucosal incisions are extended in the direction of the long axis of the stomach to their point of projection on the greater curvature where they unite. Mucosal flaps about $\frac{3}{8}$ of an inch in width are dissected back on both the stomach and pouch sides of the mucosal incisions. The flaps on the stomach side of the incision are sutured to each other, as are those on the pouch side. The stomach is then completely closed off by suturing together the stomach aspect of the initial incision. Similarly, the pouch aspect of the initial incision is closed off, leaving, however, a small opening at its greater curvature angle for the pouch mouth. The pouch mouth is

then brought up through a small counterincision in the abdominal wall.

Edward E. Jemerin.

CHEEVER, DAVID.

Innocent Gall Stones or Harmful Cholecystectomy. New Eng. Jour. of Med., Nov. 10, 1938.

Dr. Cheever feels that there is no such thing as an innocent gall stone or a harmful cholecystectomy therefore: all gall stones are potentially harmful and should be removed since cholecystectomy itself can be attended by a very low mortality rate.

Some of the statistics in the literature quote the incidence of gall stones in routine consecutive autopsies as 32.5 per cent and the presence of cholecystitis in 59.6 per cent of cases. He cites a number of personal cases wherein he feels operation at the time when the disease was first diagnosed would have diminished the hazard attending later operation.

He feels that the gall bladder symptoms following a pregnancy indicate cholecystectomy. To further his contention, he analyzes 109 operative fatalities in gall stone disease seen at the Peter Bent Brigham Hospital. In half of these cases there was sufficient warning to enable an early diagnosis to be made and operation performed before the occurrence of secondary complications which were the essential causes of the fatalities. With a mortality of .8%, such as he has in primary operations, as contrasted to a mortality of 4.1% where disease had gone beyond the gall bladder and involved the common duct, the advantages of early operation are obvious. He minimizes the possibility of postoperative adhesions and of any physiological disturbance following cholecystectomy.

Henry H. Lerner.

COLCHER, A. E.

New Displacement Technique for Gastric Mucosal Relief. Acta Radiologica, Vol. 29, 5, 615, 1937.

The author uses a Trendelenburg position for studying the mucosal relief of the stomach. The normal barium mixture is used. An adaptable fluoroscope is used, which has head and shoulder rests. Foot straps are applied over the insteps. In this manner, the patient can be kept in position with least amount of discomfort and can be rocked from a vertical position down to a Trendelenburg position of not less than 45 degrees.

Among the routine mucosal pictures the author publishes a case of scirrhous carcinoma, which showed a finely mashed honeycomb appearance of its surface.

Franz J. Lust, New York.

IMPROVING SALICYLATE MEDICATION

Salici-Vess

FORMULA:

Each tablet contains

Sodium Salicylate.....	7½ grs.
Sodium Iodide.....	1 gr.
Citric Acid.....	17 grs.
Sodium Bicarbonate.....	25 grs.

When dissolved, each tablet gives approximately 4 grains free Sodium Bicarbonate and approximately 24 grains Sodium Citrate.

Combines two established anti-rheumatic agents enhanced by effervescence and protective alkali buffers.

The Combined Effect

"The salicylates... are useful for their analgesic properties. If used, they may be combined with the iodides in one mixture." (1)

Improved Tolerance

New and Non-Official Remedies (2) confirms the value of associated alkali therapy as follows: "In practice these compounds (of salicylic acid) are not superior to sodium salicylate, which does not produce direct gastric irritation when properly guarded by a bicarbonate."

Supplied in convenient, effervescent tablets. Tubes of 30.

VI-SYNERAL

WHERE DIAGNOSIS
IS DOUBTFUL

Malnutrition

May Be the Root of the Evil

PRESCRIBE
VI-SYNERAL

McLESTER¹ asks, "Is it not possible that a great deal of the vague ill health seen today . . . is produced by marginal diets in which the quotas of minerals and vitamins are grossly suboptimal?" LEAGUE OF NATIONS² answers, "The Commission recognizes the fact that the deficiencies of modern diets are usually in the protective foods (foods rich in minerals and vitamins)."

That evasive diagnosis, where you are unable to place your finger on the exact ailment or cause of

the patient's ill health, may very well be due to a lack of protective vitamins and minerals, proven inadequate in the average diet.

Minerals with Vitamins Give Optimal Results

VI-SYNERAL* contains all the definitely recognized vitamins,¹ fortified with eight essential minerals because

- ... vitamins need one another for best results
- ... minerals are essential to optimal vitamin effectiveness
- ... vitamin and mineral deficiencies are multiple.

There is a standardized Vi-Syneral potency for every age group. Each box of 50 capsules equals the vitamin and mineral value of hundreds of pounds of fresh vegetables, fruit, milk and other foods.

*Trade Mark Reg. U. S. Pat. Off.

¹Southern Medical J., August, 1938.

²Report of League of Nations Health Committee, Dec. 6, 1935.

The original scientific formula of Vi-Syneral, pictured above in symbolic form, was developed after 26 years of vitamin-mineral research by Dr. Casimir Funk and Dr. H. E. Dubin.

RAVDIN, I. S.

Factors Involved in the Retardation of Gastric Emptying After Gastric Operation. Pa. Med. Jour., 41, 695-700, 1938.

Fluoroscopic evidence of the failure of the stomach to empty after reconstruction or short circuiting operations cannot be accepted as evidence that a mechanical defect of the anastomosis exists which will permanently retard normal gastric emptying. Under most favorable circumstances, a newly made stoma may not function for some days after operation. Fortunately, evidences of retention disappear in most cases, and gastric lavage affords relief until the stoma gives evidence of functioning.

The author then analyzes the following factors which have been held responsible for persistent post-operative vomiting:

1. Presence of bile and alkaline duodenal juices in stomach. This is disproven by well-being of patients after cholecysto-gastrostomy.
2. Spur at anastomotic site due to dropping downwards of afferent and efferent loops, producing a sharp kink, thus directing fluid from afferent loop into stomach. The incidence of this factor has been greatly reduced recently by suturing the bowel to the stomach for some distance on either side of the stoma, avoiding acute kinking.
3. Anti-peristaltic implantation of jejunum (as in original Wolfier operation) probably over exaggerated as a factor since such an operation in the dog is followed by perfectly normal emptying.
4. Other factors mentioned by various authors are: use of long jejunal loop, valves of gastric mucous membrane, closure of stoma by newly formed adhesions, compression of efferent loop by colon.
5. Recently, intussusception of jejunum was shown to be a cause of stomal obstruction, but occurs some time after recovery from operation, after period of normal gastric emptying.
6. Spasm at stoma site—Ravdin proved results were not encouraging when he used large amounts of drugs, whose primary purpose is relief of smooth muscle spasm. Therefore, if there is spasm, it is of minor importance.

Ravdin advances three other factors:

1. Interference with nervous innervation attending many resection.
2. Presence of edema at anastomotic site (with or without resection) due to trauma.
3. Edema of serum protein deficiency, especially if patient suffers from prolonged dietary deficit, due to: a. prolonged medical regime, b. self-imposed restriction—due to pain or vomiting or both. Coincidental dehydration often masks the hypoproteinemia and the true state is unrecognized until fluids and large amounts of NaCl are given, which precipitate and intensify the edema.

The author claims that edema of truma plus that due to hypoproteinemia together produce sufficient swelling of stomal site to account for more failures of gastric emptying after Bilioth I and II operations than are due to technical defects of anastomosis.

He experimentally produced hypoproteinemia in dogs by restriction in diet and plasmapheresis, keeping protein intake to 1%, but giving sufficient vitamin. As serum protein fell, gastric emptying time prolonged (shown by fluoroscopy) in both operated and unoperated dogs. In man, there is probably also added vitamin deficiency; if due to B₁₂ lack, gastro-intestinal atony results.

Ravdin concludes: 1. Pre-operative serum protein determinations should be done, while fluid-salt balance is being restored. If level approaches critical level for edema, patient should receive 1 or more transfusions of whole blood or serum.

2. Pre-operatively, put Abbott-Rawson tube in stomach. After completing anastomosis, distal valve is drawn into

The Vitamins of Cod Liver Oil ... PERIOD!

WE MEAN the kind of period that you put at the end of a sentence. The kind that means "the end—that is all—nothing more"—because we feel that that is the best description of White's Cod Liver Oil Concentrate—the vitamins of cod liver oil and nothing more—no disagreeable taste due to fatty, superfluous oils, no unpleasant odor, no digestive difficulties.

White's Cod Liver Oil Concentrate—Council-Accepted, ethically promoted, and available in

three palatable, potent dosage forms—is a source of the vitamins of cod liver oil that fits into a medical practice.

The patient appreciates the agreeable taste and convenience—the physician appreciates the approved potency and ease of administration—with the result that White Laboratories are today one of the world's largest users of cod liver oil for pharmaceutical purposes. White Laboratories, Inc., Newark, New Jersey.

distal jejunal loop. Can thus keep stomach empty and also use distal valve as jejunostomy for feeding.

3. Supply serum protein components. Recently, amino acids have been used intravenously. Lyophilized serum has also been used to raise serum protein level. Protein hydrolysate is absorbed when given by intestine.

4. Administration of salt and fluid must be carefully controlled, during the time of impaired gastric emptying, to avoid prolonging and accentuating tissue edema.

Albert Cornell.

JEMERIN, EDWARD E. AND HOLLANDER, FRANKLIN.

Gastric Vagi in the Dog. Erroneous Assumption of Uninterrupted Vagal Innervation in the Pavlov Pouch. Proc. Soc. Exp. Biol. Med., 38, 139, 1933.

According to Khigine and Pavlov, the anterior vagal trunk to the dog's stomach descends the lesser curvature to the pylorus. The posterior trunk, however, descends the greater curvature, to the middle of the pars pylorica. Pavlov devised a gastric pouch on the basis of this vagal anatomy, so that the posterior vagal trunk would descend into the pouch mucosa uninjured. The pouch, with blood and nerve supply intact, would therefore respond to all stimuli with a secretion comparable to that of the stomach proper.

The foregoing nerve distribution differs from that found in the human, where both the anterior and posterior trunks are found to course along the lesser curvature of the stomach. It was therefore thought wise to repeat the dissections in dogs. Dissection of 20 dogs consistently showed Khigine and Pavlov's anatomical concept to be erroneous. A constant architecture was found consisting of the following: On the esophagus the left and right vagal trunks divided into ventral and dorsal branches. The ventral branches united to form a ventral trunk, the dorsal to form a dorsal trunk. The trunks entered the abdomen through the esophageal hiatus in the diaphragm. Both the ventral and dorsal trunks then descended the lesser curvature on their respective stomach surfaces symmetrically with one another to about one inch from the pylorus. Each gave off branches to its respective stomach surface, the branches passing transversally to the long axis of the stomach and disappearing in the musculature about 1/3 of the way across the stomach. No branch was seen to descend the greater curvature as described by Khigine and Pavlov.

Roughly, then, 75% or more of the vagal supply to a Pavlov pouch would be transected by the incisions recommended by Pavlov. While innervation of the entire pouch mucosa might conceivably be effected by microscopic lateral branches or through myenteric

An Aid To Normal Bowel Function . KARAJEL

KARAJEL prepared from Karaya Gum is processed to provide prolonged hydration in the intestinal tract.

KARAJEL produces a moisture retaining jelly-like bulk, smooth and non-irritating. Encourages normal peristalsis and develops easily expelled, well-formed stools.

Patients with constipation of all types, who do not have organic diseases, can resort to it for longer periods of time.

There are four types of KARAJEL: KARAJEL Plain; with Belladonna; with Belladonna and Phenobarbital and with Vitamin B.

Presented as a prescription item to the medical profession only.

plexuses, it is equally likely that physiological action would be limited to the apparent sphere of influence, the pouch fundus. In the latter case, one would be dealing with an incompletely innervated pouch, and it might be expected that the response of such a pouch to vagal stimuli would be equally incomplete.

Data available in the literature were insufficient to indicate whether or not Pavlov pouches did respond completely to vagal stimuli despite the anatomical considerations elucidated above. To determine whether there exists a physiological parallel to the observed anatomical deficiency a technique is required for the quantitative determination of degree of vagal response. This must then be applied to Pavlov pouches, to Heidenhain pouches and to pouches which are made according to another technique which will leave the vagal supply uninterrupted.

ROBINS, SAMUEL A. AND ALTMAN, WILLIAM S.

The Significance of the Lateral View of the Rectum. A Description of Technique and its Value. Am. Jour. of Roent. and Rad. Ther., Vol. 40, pp. 593-605, No. 4, 1938.

Re-emphasizing a well known, but too often unobserved detail in roentgenographic studies of the large bowel, the authors present this paper with several illuminating cases. They point out that lesions in the rectum can often be demonstrated in a lateral view; whereas, the routine anterior-posterior view may miss them. This is to a great extent an indictment of the fact that too often we fail to heed the well-voiced dictum that the sole difference between the specialist and the practitioner lies in the fact that the former inserts his finger into the patient's rectum. Any lesion that has obtained a size sufficiently large to produce a defect demonstrable by X-ray ought to be amenable to diagnosis by the digit. The value of the proctoscopic examination is obvious in such instances.

Going beyond their title, the authors show instances of carcinoma of the sigmoid, splenic flexure, and descending colon demonstrated only in the lateral view.

The sole importance of this paper lies in the fact that anyone doing roentgenographic work should not be satisfied with the routine procedure hitherto pursued in studying the colon. The authors suggest that after the usual prone and oblique films are taken that a left lateral exposure be made. In this view, the rectum and sigmoid, which are often obscured by redundant loops of bowel, are clearly visualized. They fail to make mention of the use of the double-contrast enema which in many instances has

proved its value in the diagnosis of single polypoid lesions in the rectum or colon.

Henry H. Lerner.

ZDANSKY, ERICH.

Roentgenological Findings in Achylia Gastrica. Fortschr. a. d. Gebiet d. Roentgenstrahlen, Vol. 56, 5, 635, 1937.

The author describes, besides 2 cases of carcinoma of the stomach, another case, which was observed for 15 years. The patient had an achylia with normal or slightly hypochromic anemia. The X-ray examination showed hyperplasia of the stomach mucosa which was similar to a tumor. The hyperplasia gradually subsided with a decreasing of the clinical symptoms. The author emphasizes that these cases are not too rare.

Franz J. Lust, New York.

ODQVIST, HENNING.

X-ray Findings in a Neurinoma of the Stomach. Acta Radiologica, Vol. 18, 1, 101, pp. 112-118, 1937.

A case of gastric neurinoma is described, which showed clinical signs of bleeding, but otherwise only indefinite dyspeptic discomfort. The roentgenological examination revealed the presence of a well circumscribed tumor with a naval-like niche.

Franz J. Lust, New York.

NEUTRALIZES without alkalizing stomach contents

NAVITOL

AS A POTENT SOURCE OF NATURAL VITAMINS

A and D

NAVITOL is a blend of highly refined fish liver oils of such potency that it can be given in drop dosage or in 3-minim capsules. Navitol contains, per gram, not less than 55,000 units of *natural* Vitamin A and 10,000 units of *natural* Vitamin D (U. S. P. XI).

Navitol is economical to use—the cost of the usual dose of ten drops is but nine-tenths of a cent per day when purchased in the 50-cc dropper bottle.

Navitol is widely used in drop dosage as a prophylactic against rickets during infancy and, during childhood, for its favorable influence on calcium—phos-

phorus metabolism. It also supplies an abundance of Vitamin A.

Navitol in *capsule form* is used as a routine diet supplement for expectant and nursing mothers, also for older children, adults, and convalescents. One capsule is equivalent in Vitamin A and D potency to 10 drops of the oil, supplying 9,100 units of Vitamin A and 1,700 units of Vitamin D (U. S. P. XI).

Navitol is supplied in 10-cc. and 50-cc. bottles, with dropper adjusted so that 10 drops have a volume of approximately 0.2 cc (3 minims). Navitol capsules are supplied in boxes of 25, 100, and 250

Simplify Diet Problems with Horlick's

PLANNING diets to meet rigid requirements yet provide adequate nourishment is difficult. Many physicians solve this problem by using HORLICK'S, the Original Malted Milk. Horlick's is used because:

1. Its low-curd tension makes it easier to assimilate.
2. It provides an adequate supply of muscle-building protein, with the fat in an easily digested form.
3. It affords protective minerals and vitamins.
4. Its carbohydrates are easily assimilated and are in forms which discourage intestinal putrefaction.
5. It is made to laboratory standards of purity.

Infants and children, nursing mothers, the sick, the convalescent and invalids alike, relish its uniquely delicious flavor. Write Horlick's, Racine, Wis., for a trial supply.

The Effect of Anterior Pituitary-Like Hormone on Gastric Acidity in Man*†

By
HENRY FELSON, M.D.
and
LEON SCHIFF, M.D.

With the technical assistance of
ELLEN S. GABER, M.S.
CINCINNATI, OHIO

THE relationship of sex hormones and gonadotropic hormones to gastric acidity in man appears to be one of much interest due to the fact that modal gastric acidity in man is higher than in woman and that acidity is more frequent in the female (Bloomfield). In a previous communication we reported no effect on gastric acidity following the repeated intramuscular administration of estrogenic hormone ("Theclin"). We were eager to determine next the effect of anterior-pituitary-like hormone on gastric acidity because of

were instructed not to swallow any saliva. A Rehffuss tube was introduced into the stomach and the fasting contents were withdrawn. One-half milligram of histamine phosphate‡ was given subcutaneously and continuous aspiration carried out for a total of one hour; the juice collected being divided into ten minute period samples. The volume as well as the acidity of each sample was recorded. The presence of bile and

Fig. 1

its gonadotropic qualities. This hormone has been reported by Winkelstein to produce no constant effect on the gastric secretion of the dog.

METHOD USED

Four patients and three controls were selected for study. Three were males and four females. The ages varied between twenty-two and sixty-one years. They all reported to the laboratory in a fasting state. They

Fig. 2

mucus was noted. Free acidity was determined by the standard method of titrating with N/10 NaOH using Toepfer's reagent as an indicator.

A control period of observation preceded the institution of treatment varying from one week in some cases to eight months in one case and included at least three analyses. In one patient, twenty-four control analyses were performed. Normal acidity was present in three of the subjects, diminished acidity in three and increased acidity in the remaining one. During

treatment, analyses were usually done at weekly intervals, though in some instances the intervals were longer. After cessation of treatment, weekly analyses were continued for approximately two months in two cases and eight months in a third.

sisted for seventeen and nine weeks respectively. Case 2 showed no change until six weeks after treatment was ended, at which time a drop of fifty occurred which persisted for fourteen weeks. Because this decrease occurred after treatment was discontinued and

TABLE I
Data on patients receiving anterior pituitary-like hormone

No.	Age	Sex	Diagnosis	Duration of Treatment (Months)	Number of Injections	Number of Gastric Analyses	Duration of Study (Months)	Gastric Acidity Before Treatment
1	37	M	Mucous Colitis	7	150	35	14½	Normal
2	43	M	Duodenal Ulcer	5	130	74	21	Normal
3	44	M	Duodenal Ulcer	4½	103	18	4½	Decreased
4	61	F	Chronic Cholecystitis	9½	100	23	11½	Normal
5	30	F	Normal (Castrate)	8	79	22	12	Increased
6	41	F	Normal (Menopause)	1½	33	13	5½	Decreased
7	22	F	Normal	2½	32	10	2½	Decreased
Av	39			5.4	89.6	27.9	10.1	

Injections consisted of 1 cc. "Antuitrin-S"§ given subcutaneously into the upper arm. In most of the patients injections were given daily; however, in two (Cases 4 and 5) treatment was not given regularly because of lack of cooperation. The duration of treatment ranged from 1¼ to 9½ months, the injections numbered 32 to 150 and the duration of study varied from ½ to 21 months (Table I).

A total of 195 analyses was performed. Composite curves of volume and acidity of gastric juice obtained before, during and after treatment are given in Fig. 1. A slight lowering of volume and free acidity occurred during treatment followed by a slight rise after treatment was discontinued. It is felt, however, that the changes are too small to be significant.

Curves of maximum free acidity for any one ten minute collection period (on a given day) together with total volume of gastric juice obtained in the entire one hour periods are depicted in Fig. 2. Volume appeared to be unaffected except for a persistent slight lowering in Case 2 which occurred ten weeks after treatment was begun. It may be seen that two cases (3 and 4) showed an increase of 30 in maximum acidity six and three weeks after treatment was begun which persisted for practically twelve weeks and thirty-five weeks respectively (at which time treatment was discontinued). Two cases (1 and 5) showed a decrease of 30 in acidity nine and eighteen weeks after beginning of treatment which practically per-

was later followed by a rise to the original level, it is felt that it may have occurred spontaneously.

The immediate effects of injections of "Antuitrin-S" on gastric volume and acidity were observed in five patients. Fourteen analyses were done in which the administration of histamine was immediately preceded by subcutaneous injection of 1 cc. of Antuitrin-S without any unusual effect on gastric secretion.

In only one individual receiving repeated injections of Antuitrin-S (Case 6) was any untoward reaction observed. This subject was in beginning menopause and experienced metrorrhagia and dysmenorrhea which became so marked that treatment had to be discontinued.

SUMMARY

The subcutaneous administration of anterior pituitary-like hormone (Antuitrin-S) to a group of seven individuals in daily doses of 1 cc. for a total of 32 to 150 injections produced no constant effect on the volume and acidity of gastric juice as obtained in a one hour period following the subcutaneous administration of histamine.

Observations on the Incidence and Cause of Fever in Patients* with Bleeding Peptic Ulcers

By

L. V. DILL

and

C. E. ISENHOUR

NASHVILLE, TENNESSEE

KRONER (1) 1926 in a review of the literature called attention to the paucity of comment on the rise in temperature that may occur in patients with peptic ulcer. He pointed out that very little is known concerning either the incidence or cause of this fever.

Table I summarizes the data available in the litera-

TABLE I

Summary of the available data concerning the incidence of hemorrhage and fever in peptic ulcer

Author	Number of Cases	Presence of Hemorrhage	Presence of Fever		
			All Cases	Non-Bleeding	Bleeding
Lorenz	179		24%		
Kroner	300	8%	18%	16%	58%
Bang	358	42%	51%	7%	91%
Purjesz	350	30%			73%

ture on the incidence of fever in patients with peptic ulcers, bleeding and non-bleeding.

Although others had observed that patients with bleeding gastric and duodenal ulcers often had fever (2) Kroner (1) states that Lorenz was the first to study the incidence of pyrexia in such patients. Lorenz reported a series of 179 patients, 21 per cent of whom had fever. Kroner, reporting from Strauss'

Sex Incidence	75% males	74% males	80% males	45% males

Clinic in Berlin, found that 18 per cent of 300 ulcer patients had temperatures which exceeded normal at least once during their stay in the hospital. One year later Bang (3) of Copenhagen, in a study of 358 cases

*The Department of Medicine, Vanderbilt University, School of Medicine, Nashville, Tenn.
Submitted July 11, 1938.

of peptic ulcer personally observed, found that 50 per cent had sustained rises of temperature. He believed that the presence in his series of a relatively large number of active, bleeding ulcers accounted for the discrepancy between his figures and those of the

TABLE III

Percentage with Fever	53%	46%	80%	37%

earlier authors. It is to be noted that these figures pertain to all ulcer cases, and that the incidence of bleeding varied greatly in the different groups. In Kroner's series 8 per cent of the patients had hematemesis and of those 58 per cent had fever (at least one temperature observation well above normal). Only 16 per cent of the non-bleeding cases were febrile. In Bang's series hemorrhage was noted in 42 per cent and 91 per cent of these had prolonged rises of temperature, although in a small number of these cases it was impossible to rule out the effect of medi-

cation. Only 7 per cent of the non-bleeding ulcer patients were febrile. Purjesz (4) reporting on 380 ulcer patients, found that 30 per cent were bleeding and 73 per cent of these had a rise of temperature above 37.0° C. by axilla.

The cause of fever in peptic ulcer has been variously ascribed to absorption of methemoglobin or blood degradation products, reduction in blood volume, anemia, asthenia or shock with resulting increase in lability of the heat regulating center, and to gastritis. The absorption of blood from the intestinal tract was assigned as the cause of the fever as early as 1887 by

Eichorst. Leichtenstern (5) went so far as give to "absorption fever" the name, "Febris Methematomica." He stated vaguely that it was "a fever that sometimes is quite mild, sometimes rather high, sometimes perfectly atypical, irregular and remittent,

Purjesz (4) found that a definite rise in body temperature occurred following the reduction of blood volume in dogs by bleeding and he produced anemia and fever in dogs with phenylhydrazine. He interpreted these results as indicating that blood loss was a definite

TABLE V

sometimes continuous for several days," and added that it appeared 2 or 3 days after the occurrence of the hemorrhage in association with constipation. Kroner (1) noted that very large hemorrhages were almost always accompanied by fever and that young patients had less fever than the older ones. He considered the size of the hemorrhage the important factor in determining the extent of the temperature elevation. Riegel (11) states that many observers considered fever in peptic ulcer as being due to toxic or infectious material or to a ferment caused by red blood cell destruction. Others believed that the anemia itself caused dysfunction of the heat regulating center. Krehl (11) postulated similarly that the products resulting from the disintegration of red blood cells entered the blood stream and affected the heat regulating center through the vegetative nervous system. He also suggested that anemia alone could cause the fever and cites as evidence the increase in body temperature often seen in pernicious anemia and hemolytic jaundice. Jacobs (11) thought that generalized body weakness could increase the liability of the heat regulating center. Bang (3) felt that the fever could be reasonably referred to the gastritis which accompanies ulcers. The observations of Lange (6), Faber (7), Askanazy (8), Konjetzny (9), Kalima (10) and others indicate that gastritis is not an uncommon occurrence.

factor in the production of fever in patients with bleeding ulcers.

We became interested in the problem after noting that the opinions expressed in the literature were at variance, and that none entirely coincided with the impressions gained from the study of patients in this clinic.

CLINICAL MATERIALS AND METHODS

All cases of peptic ulcer studied in the Vanderbilt Hospital from the year 1925 through 1936 were reviewed, and from these 199 patients with peptic ulcers, proven by X-ray, laparotomy, or both were chosen. Each patient had been observed in the hospital for more than three days and was known, within the limits of error, to have no intercurrent infection.

The material was divided into three groups: Group 1 consisted of 155 patients with peptic ulcers whose stools did not contain occult blood, and who gave no history of recent bleeding. Group 2 consisted of 44 patients whose stools gave strong reactions for occult blood and who had, for the most part, come into the hospital with complaints referable to hemorrhage. A control group (Group 3) was composed of 78 patients with complaints referable to the gastro-intestinal tract, in whom no organic disease could be demonstrated and who were diagnosed as having gastric neuroses.

TABLE VI
The incidence of ulcers, hemorrhage, and fever in relation to the duration of ulcer symptoms

	Bleeding Cases			Non-Bleeding Cases		
	Group 1 0-2 years	Group 2 3-10 years	Group 3 11 plus years	Group 1 0-2 years	Group 2 3-10 years	Group 3 11 plus years
Number of Cases	9	26	9	57	60	37
Massive Hemorrhage	4	13	6	—	—	—
Moderately Severe Hemorrhage	2	8	1	—	—	—
Small Hemorrhage	3	5	2	—	—	—
Presence of Fever	7 (77%)	20 (77%)	16 (89%)	16 (47%)	26 (43%)	19 (51%)

"Fever" in our studies was arbitrarily defined as any rise in temperature above 99.0° F. which was sustained for more than two days, any rise to 99.2° F. or above for two days, or any single rise exceeding 100.0° F. The temperature of each patient was taken

TABLE VII

The incidence of fever in bleeding and non-bleeding ulcer patients with and without anemia

	Patients With Bleeding Ulcer		Patients With Non-Bleeding Ulcer	
	With Anemia	Without Anemia	With Anemia	Without Anemia

Presence of Fever	13 (93%)	23 (74%)	4 (100%)	64 (46%)

every four hours during the day, and, in the presence of fever, at the same intervals at night. All patients had blood studies on admission to the hospital, including red blood cell counts, white blood cell counts, hemoglobin determinations, and a differential count of the stained leucocytes. In the presence of hemorrhage frequent hemoglobin determinations, red and white cell counts were done. Stool examinations were made in practically all instances when the patients were first admitted to the hospital, and when patients were found to be bleeding, stool examinations were made at frequent intervals thereafter.

The age of each patient was determined by the age given on admission to the hospital and the duration of symptoms was determined from the hospital record.

The amount of diarrhea, vomitus and fluid intake was considered in reviewing the records and particular attention was paid to dehydration. The influence of treatment on the temperature was carefully considered in each instance and all cases in which medication or dehydration was believed to be in part or wholly responsible for the fever were discarded.

The studies on the relation of anemia to the presence of fever in ulcer patients were confined to a group of individuals who had less than 2,500,000 red blood cells or 7.5 grams (50 per cent) of hemoglobin.

CLINICAL OBSERVATIONS

Clinical Data. In order to define clearly the type of clinical material reviewed in this study of fever in peptic ulcer the case histories were analyzed with reference to age, incidence of hemorrhage, duration of symptoms, and sex distribution. (Table II)

In this series the average age of the patients was forty-

five years. The average age of those with non-bleeding ulcer was forty-five years, with bleeding ulcer was forty-four years. The patients of the control group (gastric neuroses) were slightly younger, the average being thirty-seven years. The incidence of bleeding in the ulcer group was 22 per cent.

The average duration of gastro-intestinal symptoms among the patients with ulcer was 8.2 years; in patients with non-bleeding ulcers the average duration of symptoms was 8.4 years, and in those with bleeding ulcers 7.6 years. Symptoms in the gastro-intestinal neurosis group averaged 6.1 years duration.

Males had peptic ulcer three times as frequently as females (75 per cent) in our series and this ratio was maintained in both bleeding and non-bleeding groups. The gastric neuroses showed only a slight preponderance of females (55 per cent).

Incidence of Fever. 106 of the 199 patients of the entire series, or 53 per cent, had fever, temperature elevations which satisfied our criteria for the term. Of 155 non-bleeding ulcer patients there were 71 who had fever (46 per cent). Thirty-five of the forty-four patients with bleeding ulcers, or 80 per cent, were febrile. Fever was present in 37 per cent of patients in the gastric neurosis group. (Table III)

Factors Affecting Fever. In order to see what effect the size of the hemorrhage had on the temperature the cases were classified as examples of either massive, moderate or small hemorrhage. These lines of division were arbitrarily drawn and were none too easily defined, but patients were thus classified on the basis of the impression gained from a complete resume of history, physical examination, and laboratory findings.

The findings in Table IV indicate that in hospitalized patients massive hemorrhages are present or are recognized more frequently than moderate or small ones. Fever as we have defined it is somewhat more commonly encountered and is of longer duration in patients after moderate or large hemorrhages than after small ones.

In order to study the relation of age of the ulcer patients to the occurrence of hemorrhage and fever, the patients were divided into three age groups: 0-20 years, 21-40 years, and from 41 years upward. Table V indicates that the incidence of hemorrhage for peptic ulcer increases with age and that among adult patients fever occurred more frequently in bleeding than in non-bleeding ulcers. The number of patients in the 0-20 year group was too small to permit comparison with the other groups.

An attempt was made to correlate the duration of the ulcer symptoms with the presence or absence of fever. To this end patients were divided into bleeding and non-bleeding groups and each group was separated into three age periods: Those who had symptoms from 0-2 years, from 3-10 years, and from 11 years

TABLE VIII

The influence of fever and hemorrhage on the leucocyte counts of ulcer and neurosis patients

Average Leucocyte Count	All Ulcer Patients	Non-Bleeding Ulcer Patients		Bleeding Ulcer Patients		Control Group (Gastric Neurosis)
	7,871	7,642		7,973		6,975
		afebrile	febrile	afebrile	febrile	
		7,552	7,932	8,224	7,900	

Chart 1. A composite graph, showing the effect of bleeding on the temperature of five dogs.

upward. A study of Table VI indicates that slight if any effect upon the incidence of fever can be attributed to the duration of the ulcer. As in previous charts the effect of hemorrhage on the incidence of fever is noteworthy.

In Table VII it is seen that over 90 per cent of the patients with bleeding ulcers and low hemoglobin values had fever. Four patients with non-bleeding ulcers but with anemia, also had fever. These figures appear to be significantly higher than those for patients with ulcers, bleeding and non-bleeding, but without anemia. Anemia, therefore, seems to be significantly related to the temperature levels exhibited by ulcer patients.

Leucocyte Counts. A comparison of the leucocyte counts in the various groups is noteworthy only because of the absence of significant differences. (Table VIII)

EXPERIMENTAL

Material and Methods. An attempt was made to duplicate in dogs the conditions existing in patients with bleeding peptic ulcers in so far as reductions in blood volume and the presence of blood in the gastro-intestinal tract are concerned and to study the effect of these factors, singly and in combination, upon the temperature of the animals. Dogs of varying size were used and were divided into four groups. In order to determine the effect of massive blood loss on the body temperature, each of five dogs (forming Group I) was bled from the femoral artery one-quarter of its estimated blood volume.* Twenty gauge needles were used and sterile technique was employed. Four dogs (Group II) were given, by stomach tube, blood

Chart 2. A composite graph showing the effect of giving blood by stomach tube on the temperature of four dogs.

Chart 3. A composite graph showing the effect of bleeding and of giving blood by stomach tube on the temperature of six dogs.

approximating one-quarter of their blood volumes, in an effort to evaluate the role played by blood in the intestinal tract. In order to combine the factors existing in Groups I and II, six dogs, forming Group III, were bled one-quarter of their estimated blood volumes and fed this same blood immediately by stomach tube. Group IV, including five dogs, was used to determine the effect upon the body temperature of the reaction which may occur as the result of arterial puncture. The femoral arteries of these animals were punctured.

Temperatures were taken rectally twice daily (at 8:00 A. M. and 4:00 P. M.) for five days preceding and ten days following each procedure. Only the maximum temperatures for each day are recorded in the charts.

EXPERIMENTAL OBSERVATIONS

Reduction in Blood Volume. The animals of Group I whose blood volumes had been reduced by 25 per cent experienced a rise of temperature, shown in a composite graph (Chart 1) of only 0.1° F. above the control level for that group.

The Presence of Blood in the Gastro-Intestinal Tract. Chart 2, a composite graph of the temperature curves of the animals of Group II which had been fed a large quantity of blood by stomach tube, shows only 0.1° F. rise in temperature above the control level, although this was attained on three separate occasions.

Combination of Blood Volume Reduction and the Presence of Blood in the Gastro-Intestinal Tract. The composite graph (Chart 3) shows the effect of the procedure carried out on Group IV. The temperature of these animals exceeded the highest control level three times, the greatest excess being 0.7° F. However, the observations which follow indicate that this

*The total blood volume was estimated as 1/10 of the body weight.

Chart 4. A composite graph showing the effect of arterial punctures on the temperature of five dogs.

Chart 5, Case 1. The effect of blood in the intestinal tract on the temperature of Subject 1.

temperature elevation was not related to either reduced blood volume or blood in the gastro-intestinal tract.

Control (Arterial Puncture Alone). Following arterial puncture, the post-operative temperatures exceeded the control levels, the highest being 0.7°F . above the maximum for the pre-operative period. This post-operative temperature elevation was maintained for several days. (Chart 4)

In summary it may be stated that under the conditions of our experiment no significant rise in temperature was observed in dogs as a result of rapid and great reductions in blood volume, the presence of large amounts of blood in the gastro-intestinal tract, or a combination of both.

CLINICAL EXPERIMENTS

In order to note the effect of blood in the human intestinal tract upon body temperature, a clinical experiment, similar to the procedure carried out in Group I of the animal experiments was designed.

Material and Methods. The experimental subjects were a young physician and three patients who had been admitted to the hospital with afebrile illnesses and with no symptoms referable to the gastro-intestinal tract. A preliminary control period of five days was used with each patient to obtain temperature records and to exclude the presence of blood in the intestinal tract.

The blood for use in the experiments was obtained by phlebotomy from patients with congestive heart failure. It was collected, citrated, and stored in a refrigerator, under sterile conditions until used.

Moderate doses of morphine and sodium amytal were given the experimental subjects. 500 to 600 cc. of blood at body temperature were introduced into the stomachs of the sleeping patients by Levine tubes.

In order that the blood remain in the intestinal

Chart 6, Case 2. The effect of blood in the intestinal tract on the temperature of Subject 2.

Chart 7, Case 3. The effect of blood in the intestinal tract on the temperature of Subject 3 (see text).

tract as long as possible, paregoric, 4 cc. three times daily, was given for ten days. Temperatures were taken orally every four hours during the day. None of the subjects vomited. Occult blood was demonstrable in the stools from the second to the fourth day after the beginning of the experiment (varying as to constipation) and persisted for from forty-eight to seventy-two hours following its first appearance.

Subject No. 1. K. P., was a forty-three year old white male with multiple sclerosis. After a control period of five days, 600 cc. of blood were introduced into the stomach (Chart 5). Subject No. 2. E. G., was a forty-seven year old white male. The diagnosis was syphilitic aortitis and Adams-Stokes syndrome. After five days of control period, 550 cc. of blood were introduced into the stomach. (Chart 6). Subject No. 3. C. S., was a twenty-one year old white male, diagnosed obesity. Following a four day control period, 800 cc. of blood was introduced into the stomach. (Chart 7). Subject No. 4, a twenty-three year old white male in excellent health was given 500 cc. of blood by stomach tube following the usual five day control period. (Chart 8).

Subjects No. 1 and No. 2 showed only an insignificant rise in temperature following the introduction of blood into their gastro-intestinal tracts. Subject No. 3 did experience an elevation of temperature for the whole period, but it is noteworthy that this exceeded the maximum temperature of his control period by only 0.6°F . Subject No. 4 was afebrile save for one day. On the fourth day following the introduction of blood into the stomach this individual had nausea and vomiting preceded by generalized abdominal pain. After three hours this pain migrated to the right lower quadrant; it subsided seven hours after the onset. Appendicitis was suspected.

While no conclusions can be drawn from such a small

Chart 8, Case 4. The effect of blood in the intestinal tract on the temperature of Subject 4 (see text).

number of observations, we are of the opinion that blood in the intestinal tract of man does not of itself cause a significant rise in temperature.

COMMENT

We have determined the incidence of fever, as we have defined it, in a series of patients with proved peptic ulcers. The incidence of fever in our patients (53 per cent) is identical with the series published by Bang (3), but greatly exceeds those of Kroner (18 per cent) and Lorenz (24 per cent). We found that 80 per cent of our patients with bleeding ulcers were febrile. These figures do not differ greatly from those of Purjesz (73 per cent) or Bang (91 per cent), but are well above those quoted by Kroner (58 per cent). Our percentage of febrile, non-bleeding ulcer cases (46 per cent) is much higher than that of Kroner (16 per cent) or of Bang (7 per cent).

To explain the apparent discrepancy between his figures and those of the earlier writers Bang (3) postulated an increased activity of the ulcers, as evidenced by the high incidence of bleeding in his cases. Using this criterion in an attempt to correlate the incidence of fever to bleeding we are unable to obtain a true parallel by comparing the different series, and interpret the greater part of the variation in figures as to variations in standards of fever. It should be emphasized that we found that patients without demonstrable organic lesion had fever, according to our definition, in a significantly high percentage (37.1 per cent).

We have attempted to relate the fever occurring in patients with peptic ulcers to hemorrhage, the presence of blood in the intestinal tract, the age of the patient and of the ulcer, the presence of anemia, and the leucocyte count. Our series demonstrates that patients with ulcers have fever more frequently than patients with no demonstrable organic lesion, and that bleeding increases this tendency. The presence of anemia also increases this tendency to fever in patients with both bleeding and non-bleeding ulcers. Massive and moderately severe hemorrhages are more frequently associated with fever than are small hemorrhages. We are unable to correlate the occurrence of fever with either the age of the patient or the duration of ulcer symptoms. The absence of leucocytosis in our patients lead us to assume that infection of the base of the ulcer or an associated gastritis or duodenitis is not important in the production of this fever.

The experimental evidence seems to indicate that

little part is played in the production of fever by either blood in the intestinal tract or absorption of blood degradation products.

Our studies throw no light upon the possible influence of a labile vegetative nervous system in the causation of fever, as we have defined the word, but that this may play some role is suggested by the relatively high incidence of fever in patients with gastric neuroses.

SUMMARY AND CONCLUSIONS

Peptic ulcers, bleeding and non-bleeding, occurred most frequently in our series in males of middle age.

The incidence of bleeding in the group of patients admitted to Vanderbilt University Hospital with peptic ulcers was 22 per cent.

Fever was present in 53 per cent of all ulcer patients, in 80 per cent of all patients with bleeding ulcers, and in 46 per cent of all patients with non-bleeding ulcers. In a control group of patients in whom no organic lesion could be demonstrated, fever was present in 37 per cent.

Large hemorrhages were more frequently associated with fever than were the small ones.

The patients with peptic ulcer and anemia had fever more frequently than did those without anemia. Anemia seemed to be significantly related to the temperature levels exhibited by ulcer patients regardless of the presence or absence of hemorrhage.

In our material the incidence of fever could not be correlated with either the age of the patient or the duration of the ulcer.

The withdrawal, under aseptic conditions, of a large amount of blood from dogs does not result in fever. The presence of blood in the intestinal tract of either dog or man does not cause fever *per se*. Indeed, this study does not implicate any single causation factor for the fever which is present in the majority of patients who have bleeding peptic ulcers. It does emphasize the frequent co-existence of fever in ulcer patients with (a) the presence of blood in the gastrointestinal tract and (b) the presence of well marked anemia. The study likewise reveals the frequent occurrence of significant temperature elevations in patients with gastric neuroses. These observations suggest that the incidence of fever may be greatest in patients with bleeding peptic ulcers who have experienced large hemorrhages, are anemic, and have a labile vegetative nervous system.

The Effect of Pyloric Obstruction on the Filling and Emptying of the Gall Bladder in Cholecystography

By

MAURICE FELDMAN, M.D.
BALTIMORE, MARYLAND

A PERUSAL of the available literature reveals little if any information regarding the effect of delayed gastric emptying in cholecystography. In this brief communication a study of 21 cases of pyloric obstruction, ranging from four to twenty-four hours, with varying degrees of gastric retention has been studied following the administration of tetraiodophenolphthalein. The effect of gastric emptying on the filling and emptying of the gall bladder has been carefully observed. The etiological factors producing the obstruction at the pyloro-duodenal outlet varied, but in the majority of cases ulceration was the principle cause.

The results of filling of the gall bladder obtained in this study is presented in the table below. It will be noted that of the 21 cases, 15 filled normally, as indicated by a dense homogeneous vesicle shadow, while in 6 cases a faint or poor shadow and in 3 a non-filling gall bladder was obtained.

From these studies it would appear that for practical diagnostic purposes, pyloric obstruction is not a significant factor in the causation of non-filling of the gall bladder. Obstructive lesions at the pyloro-duodenal outlet are rarely complete, and since enough of the dye usually flows into the small intestine, incomplete pyloric obstruction should have but little effect upon cholecystography. However, in the case of complete obstruction, in which instance none of the dye passes into the intestine, non-filling of the gall bladder may be observed. This form of obstruction presents a doubtful factor in the non-filling gall bladder which should be borne in mind.

The effect of emptying of the gall bladder has also been studied (see table), following the usual egg-cream-milk meal. In the 15 normally filled gall bladders, 10 contracted normally, i.e. less than half of its original size; while in 5 the size of the vesicle was not appreciably altered. These findings therefore indicate evidence of retardation of emptying in one-third

of the normal gall bladder cases. Our studies on emptying in response to a fat meal would suggest that sluggish emptying in cases of pyloric obstruction has little or no clinical significance.

Of the 3 patients with non-filled gall bladders, 2

were surgically explored. In one instance, with a small 18 hour gastric retention, gall stones were found, and in the other case with a small 24 hour gastric retention, the gall bladder revealed pericholecystic adhesions, but was otherwise grossly normal.

History and Development of Gastric Analysis Procedure (Second Installment)

By

FRANKLIN HOLLANDER, Ph.D.

and

ABRAHAM PENNER, M.D.

NEW YORK, NEW YORK

VI. CONSTITUENTS STUDIED AND ANALYTICAL METHODS EMPLOYED

OF all the constituents of the gastric contents which interest the clinician, the acid secreted by the stomach has always been considered the most important. At first it was thought necessary to know, only in a qualitative way, whether or not free hydrochloric acid was present in the gastric contents. To this end various indicators were employed: congo red, Boas' reagent (resorcinol-sucrose), Guenzburg's reagent (phloroglucin-vanillin), methyl violet, Toepfer's reagent (dimethylaminoazo-benzene), and tropaeolin OO. At the time these various test substances were first introduced the modern physico-chemical concept of acidity was itself very young, and so the literature is replete with discussion of their relative sensitivities. These discussions were concerned with the influence of the various protein degradation products, lactic acid, phosphates, and other buffer substances—as we now designate them—and have continued even as recently as 1914 (Fittipaldi (43)).

It soon became apparent, however, that quantitative estimations of acidity were essential. It is difficult to say just when the titrimetric method was first employed in clinical gastric studies, but as early as 1886 Jaworski and Gluzinski (64) introduced the present system of estimating acidity in "degrees" or, as we now designate it, "clinical units." For these determinations they titrated their specimens with 0.1 N alkali, using litmus as one indicator. Concerning the reagent for titration there is little to say; sodium hydroxide possesses such obvious advantages that it soon replaced the iodometric method of Sahli and became the standard for all subsequent titrimetric work. The proper choice of indicators, however, was a more difficult problem to cope with and it has persisted until the present decade. This difficulty could be resolved only with a clear understanding of the significance of acid-base titration curves and the effect upon them of various buffer substances. Although the early titration work was done with the same indicators which were being used for the qualitative tests, gradually all of these were discarded, with the exception of Toepfer's reagent for free hydrochloric acid, and were replaced by phenolphthalein (e.g., Christiansen (21)). Alizarin for free and litmus for total acidity were also recom-

mended, but by this time they too have been discarded. With the introduction of the pH concept of acidity in 1909 by Sørensen, it became possible to define end-points in terms of those pH units which correspond exactly to whatever definitions of free and total acidity might be adopted. Probably the first efforts in this direction were reported by Michaelis (93) in 1917 and subsequently presented in more detail in a lecture given before the Harvey Society in New York (94). For the free hydrochloric acid end-point Michaelis recommended a pH value of 2.8, which is indicated by a salmon-pink color with Toepfer's indicator; the yellow end-point in general use today is entirely erroneous because it corresponds to a pH value of *circa* 5. For total acidity, he recommended pH 6.5, but as Shohl (125) subsequently pointed out, a value above 7 is more rational because of its proximity to the pH of blood. However, Shohl and King (126) recommended phenolphthalein, the pink color of which corresponds to pH 8-10. For free acidity titrations, they advised thymol blue in preference to Toepfer's reagent, and an end-point of pH 3.0. For routine clinical purposes, Toepfer's and phenolphthalein are probably being used more extensively today than any other combination of indicators. For purposes of investigation, however, particularly where it is important to obtain a reliable evaluation of the combined acidity as a measure of the buffer content of the gastric juice, Hollander (58) has recommended a different combination of indicators: bromphenol blue at pH 3.5, which corresponds exactly to a free acidity of one clinical unit, and phenol red at pH 7.0, which corresponds to exact physico-chemical neutrality and is therefore preferable to the higher value given with phenolphthalein. In order to obtain titration values which are precise to ± 0.1 pH units, the color of the end-point must be determined by comparison with a standard mixture of indicator and buffer solution at the desired pH—a procedure which lends itself readily to precise work with as little as 0.5 ml. of stomach contents and which we are now using routinely in our laboratory for all our clinical as well as animal investigations.

Combined acidity values are determined by the difference between free and total acidities, and are usually small; hence, unless the titrations are performed very carefully and the end-points are sharply defined the results may be extremely unreliable. For

Editors' Note: This is the second installment of this article, the first having appeared in the January, 1939 issue. The Bibliography will be published with the final installment in an early issue.

this reason, as well as the apparent lack of clinical significance, there is a general tendency to disregard the combined acidity (Martin (86), Crohn (26), Wilhelmj (139)) for most practical purposes. On the other hand, with the increasing interest which is now observable in the process of neutralization of gastric contents by duodenal regurgitation and in the non-acid secretions of the stomach, the precise determination of combined acidity may in time become a factor of some significance in gastric analysis (Hollander (59)).

Some mention should be made at this point of the units in terms of which we express acidity. The "clinical unit," or "degrees of acidity" is defined in terms of the number of ml. of 0.1 N NaOH which are titrimetrically equivalent to 100 cc. of the specimen. This definition can be traced as far back as the work of Jaworski and Gluzinski (64) in 1886. In modern physico-chemical parlance, this number is equivalent to the milli-normal concentration (mN). As such, it is more universal, because the same terminology can be applied in expressing the concentration of many of the other factors with which we deal in analyses of the gastro-intestinal fluids. For this reason the latter unit is becoming increasingly popular, and we feel that it should be universally adopted in the terminology of gastric analysis—in preference to "degrees" and "clinical units," and certainly in preference to per cent hydrochloric acid, which offer no theoretical basis for comparison with other constituents like neutral chlorides, total base, etc.

With further extension of the concepts of physical chemistry, it was not long before proposals were made to replace titrimetric determinations of acidity by determinations of pH as such. Within two years after Sorensen had published his definition of pH, Christiansen had already reported the good agreement of titration acidities in terms of millinormal units (using Guenzburg's reagent) with millinormal values calculated from pH values which he determined by means of the hydrogen-gas electrode. Similar comparisons were made by other investigators, though not always with the same results. Thus, Denis and Silverman (31) developed a satisfactory bedside technique which utilized pH test-papers; Shohl and King (126) compared titration and colorimetric pH procedures and obtained better agreement with thymol blue indicator than with Toepfer's, though neither indicator was exact; Kopeloff (73), Norgaard (98) and Vos (138) all reported the correlation between titration and pH values to be far from good. Hence, the latter investigator concluded that not only is the titration method entirely adequate for the purposes of gastric analysis, but it is also the most convenient. A similar conclusion was arrived at by Hollander (58), who pointed out that for free acidity values of the magnitude encountered in gastric analyses, the reliability of an end-concentration in milli-moles when determined titrimetrically is considerably greater than when calculated from a pH determination, be it electrometric or colorimetric. Thus, it is not surprising that pH determinations have been discontinued entirely, for purposes of both clinical and experimental gastric analysis. Furthermore, pH is a more exact physico-chemical criterion of acidity for such phenomena as pepsin activity, but so far as the activity of the acid producing cells of the gastric mucosa are concerned, it is the amount of hydrochloric acid as measured by

milli-normal concentration that is important. Where the color of a gastric sample—due to contamination by bile, for instance—is so great that exact titrimetric determination of a color end-point is impossible, there still remains the principle of electrometric titrations (e.g., see Teorell (134)). By this procedure, the end-point (say pH 3.5 for free and 7.0 for total acidity) is determined with great ease by an electrical method, using the quinhydrone or the glass electrode; but until simple and cheap commercial set-ups are available, it is not likely that this procedure will be adopted for other than experimental purposes.

In addition to the foregoing direct procedures for observing gastric acidity, there have been proposed from time to time a number of indirect methods. As far back as 1877, Szabo (131) utilized the acid hydrolysis of sugar, measured polarimetrically, to demonstrate the presence of free acid in the stomach. In 1908, Holmgren (63) developed the so-called capillary analysis method for free hydrochloric acid in gastric contents. This method was based on the distance to which a drop of acid fluid will spread in a piece of standardized filter or blotting paper, as shown by the presence of an acid-base indicator like congo red. Under properly standardized conditions, this distance is determined by the surface tension relations within the capillary pores of the paper, and these in turn are a function of the acidity. Hence, from the mathematical theory of these physico-chemical relations, it is possible to calculate the degree of acidity which occurs in each case. Unfortunately the values so obtained are in only poor agreement with those derived titrimetrically (Baumstark (8), Key-Aberg (70), Mattisson (90), Schmidt (118) and Orell (99)), and so the method has received almost no attention outside of the Scandinavian countries. In this country Kantor (65) developed a microscopic test based on the swelling of moist collagen fibrils, but this also has found little application. In view of the high quantitative reliability of acid-base titrations and the extreme ease with which they can be performed, it is easy to see why this latter procedure has replaced all others so completely.

Next to the acid content, the pepsin activity of gastric contents has usually been considered of greatest importance. Although qualitative methods were employed for some time before, the first reliable quantitative procedure was reported by Mett in Russian in 1889 and described in German in 1894 (91). It is interesting that, except for the modifications in technique introduced by Christiansen (22) in 1912, this method has been employed almost universally until within the last decade. Neither the refractometric method developed by Schorrer (119) in 1908 and proposed for clinical use by Reiss (111) in 1923, nor the method of Boas (15) which depends on the determination of the amount of starch liberated from a bit of macaroni which has undergone peptic digestion, has ever received much application. Recently, however, as gastro-enterology has become increasingly experimental, there has developed a need for more precise methods of determining peptic activity. In response to this need we now have the highly refined methods of Gilman and Cowgill (49), later modified by Osterberg, Vanzant and Alvarez (101), and of Anson and Mirsky (2). The former depends on the photometric determination of the amount of silver liberated by the digestion of a piece of photographic film, previ-

ously exposed and developed; the Anson and Mirsky method employs hemoglobin as a substrate. Although for investigative purposes we may require a quantitatively more reliable method than that of Mett, the routine purposes of clinical analyses are probably well satisfied by the older procedure. The method of Gilman and Cowgill consumes far less time than the Mett method and for this reason it may ultimately come into more general use.

On the other hand, it is noteworthy that the examination of gastric specimens for peptic activity has never been adopted extensively as a routine procedure, nor by all the signs now apparent is it likely to become so in the immediate future. Similarly with pancreatic lipase and trypsin, which are frequently found in the stomach, although all three of these enzymes are likely to be matters of physiological interest for a long time to come. Phosphate determinations have never attracted any considerable attention because this chemical radical is in no way specific to any secretion or pathological disturbance. In the case of mucus, bile, lactic acid, blood and other cellular elements the situation is different. All of these possess distinct, though not conclusive, significance as diagnostic aids. Thus large amounts of mucin may be indicative of a gastritis, but it may also be derived from the saliva in cases where the latter is excessive. The presence of bile is indicative of duodenal regurgitation, but this is now believed by many workers to be a normal physiological process (Boldyreff (17)); how extensive and important this process is, however, remains a moot question (Shay, Katz and Schloss (124)). Lactic acid is unusually indicative of gastric retention in the absence of free hydrochloric acid. But since it may occur in benign achylia retention as well as in carcinoma involving the pyloric region, the presence of lactic acid is in no way pathognomonic. Occult blood also is no specific indication of hemorrhage due to ulcer or cancer, since it is frequently encountered in superficial erosions and cases of chronic passive congestion (Pilcher (107)). Hence, there have been evolved various qualitative methods for the detection of these several substances all of which can be found in any of the standard works on clinical laboratory procedures. Quantitative methods, however, are not available for any of them, nor is their development likely since knowledge concerning the amounts of these substances is hardly likely to add to the utilitarian value of the present procedures.

Finally, let us consider the inorganic chloride content. Part of this element is secreted as hydrochloric acid, the remainder as neutral chloride from various sources: alkaline secretions of the fundus and antrum, saliva and especially the regurgitated intestinal fluids. Also, it is frequently claimed that in cases of achylia the parietal cells may secrete a fluid which contains neutral chloride and which is the unhydrolyzed precursor of the hydrochloric acid. Hence, although chloride values are no index to hydrochloric acid production, most workers have long felt that the relations between total chloride, neutral chloride and acid chloride might give a clue to the relative extents to which various phenomena are operative in the gastric fluid of any one patient. In order to determine the chloride concentration, any modification of the original Toldard titrimetric method may be employed; the most reliable of these is probably that of Wilson and R. H. (141). Among those who have conducted ex-

tensive studies of the variations in chloride concentration which occur in the course of gastric analyses, we may mention Pfaundler (104); Bolton and Goodhart (18); Baird, Campbell and Hern (5); Holler and Bloch (62); Markoff (85); Gorham, Stroud and Hoffman (53); Rudd (115), and Berglund, Johnson and Chang (11).

As yet none of these workers have been able definitely to correlate secretory disturbances with changes in chloride concentrations, in such a way as to utilize them diagnostically. Even so far as understanding the pathological physiology is concerned, we are still far from grasping their significance. This explains why chloride determinations have found so negligible a place in routine gastric analysis.

VII. PERIOD OF PHYSIOLOGICAL ANALYSIS

In our discussion of fractional analysis above, it developed that the method, though universally accepted, has not come up to expectations, chiefly because of the gradual realization that a simple, precise diagnostic procedure for gastric disease is unattainable. Instead, it has developed that what we must attempt is to study the individual components of the patient's gastric behavior, to compare these with established norms, and from the pathological deviations of these characteristics to build up a composite picture of the stomach which may then serve as a basis for diagnosis. Chief among these physiological components are the emptying time, the response to specific "psychic" and chemical gastric stimuli, the volume of pure gastric juice in contradistinction to the acidity of the stomach contents, etc. Let us, therefore, examine each of these variables in turn, and thus, perhaps anticipate the line of future development of gastric analytical procedure.

A. Emptying Time.

In 1898 Cannon first studied gastric motility and emptying by means of Roentgen rays, and a radiopaque meal for experimental purposes, but clinical use of the X-ray was not initiated until much later. As a consequence of subsequent developments in apparatus and technique, we find today that the observation of the gastric residue, six hours after the ingestion of a barium or a bismuth meal, is being employed universally as a measure of gastric motility. Previous to 1911 all efforts at estimating emptying time had been confined to gross observation of the amount of test-meal which could be removed by means of a stomach tube, say, one hour after its ingestion. In spite of the popularity of the radiographic methods, many gastroenterologists recognized very soon that a motor test-meal yields results which are physiologically and diagnostically more significant than the former procedure (Bassler (6), Levy (78), Bennett and Ryle (9)). Crohn (26) states specifically that in instances of doubt the food test should receive the greater consideration.

Now, if we are to utilize test-meal residue as a criterion of gastric emptying it is essential that both the test-meal and the conditions of observation be standardized. The earliest efforts employed dietary test-meals like those of Riegel and Ewald; subsequently Sahli (117) proposed the admixture of a fat emulsion to the test-meal thus making possible a quantitative estimate of the extent of emptying after one hour. Particulate foods like rice, raisins and currants have similarly been employed in various labora-

torics. With subsequent refinement in the use of fluid test-meals, colored indicator substances also were added; at present all of these many procedures are being employed for this purpose.

How, from this diversity of procedures, can we pick out that which is most rational? As we see the problem it should be the function of a motility test to give a *quantitative* indication of the degree of gastric retention after a specified lapse of time, and preferably at repeated intervals following administration of a test-meal. This test substance should be as nearly physiological as possible—which a barium or bismuth meal is not. A mixed dietary meal, containing some non-digestible particulate matter, approaches this ideal—except that it does not lend itself to a series of determinations at short time intervals. Concerning the latter requirement, the fluid test-meal containing a suitable colored indicator is excellent though it may well be asked how representative it is from the digestive aspect. Also, if we adopt a fluid motor test-meal, the motility and secretory tests can be done simultaneously. It remains for the future to show which of these two types of motor meal is preferable. If the emptying time data obtained from both are closely analogous, the fluid meal should be adopted because it permits of simultaneous motor and secretory studies. If they are not analogous, it is still conceivable that we may want to adopt the fluid meal because it offers a standardized, though non-dietary, stimulus and a simple and inexpensive procedure. If it should be adopted, extreme care must be given to the choice of an indicator substance; this question will be discussed further on in the section on the estimation of volume of secretion.

B. Secretory response to psychic stimulation.

In the last decade of the nineteenth century Pavlov demonstrated beyond all question the existence of a psychic or cephalic phase of gastric secretion, as distinct from a chemical phase. If knowledge concerning the secretory activity of the stomach be accepted as important for clinical purposes, it is essential that we take cognizance of differences in pathological function which may exist between these two phases. This differentiation is all the more important in the light of our modern theories concerning the etiology of peptic ulcer, which place so much emphasis on the nervous or psychic factor. Therefore, the matter reduces to a search for an adequate criterion of psychic stimulatory activity as distinct from chemical stimulation.

As long ago as 1901, Schüle (122) studied the response of patients to coffee kept in the mouth for five minutes and then expectorated. In 1910, Curschmann (28) concluded that individual variations in response to a given test-meal might be ascribed to the fact that the test-meal proved unappetizing to the patient. To offset this, he offered the patient free choice of the meal to be used, and obtained results which he thought were significant, especially in cases of gastric neurosis. However, so far as the development of a specific psychic stimulus which will have universal applicability is concerned, the problem is probably insoluble. Hypnosis has been proposed, but it does not lend itself to routine application. The sight and odor of a tempting meal also offers obstacles in that the meal must vary with the previous conditioning of the individual and his response at any one time, even to the same meal, must be subject to numerous disturbing

psychological influences. Winkelstein, at our hospital, employs a procedure based on the chewing and expectoration of an orange—which seems to approach the desired end for a simple and direct psychic stimulus.

It may be, however, that instead of a direct stimulus of this kind, the best criterion of psychic secretory activity can be established without any specific stimulus at all, i.e., on the basis of the "continuous secretion." This would involve the periodic evacuation of the resting stomach by means of a duodenal tube; the obvious objection, based on possible mechanical stimulation of the mucosa by contact with the catheter, we now know to be invalid. The method has already been utilized by Galambos (46), Pollard and Bloomfield (108) and Schreiber (120). An excellent study on six normal young adults (female), extending over periods of one to six hours, has also been reported by Hellebrandt, Grant and Catherwood (57). The night secretion in response to a regular mixed meal, as utilized by Winkelstein (142) and others, does not satisfy the requirements of a pure psychic test and for this reason cannot find application in this connection. Of course, in applying a test based on the continuous secretion which is non-specifically stimulated, it is of the utmost importance that the patients' environmental conditions be properly maintained. But this, like a number of other factors, require further study and standardization before we can be sure that such a procedure can be used as a valid test of cephalic phase activity. We feel that the problem is of sufficient importance to merit the attention of clinical investigators in the very near future.

C. Secretory Response to Chemical Stimulation.

In contradistinction to the psychic phase of secretion there exist two chemical phases—the gastric, which is intermediated by gastrin from the antral mucosa, and the duodenal, which is effected by the intestinal absorption of secretagogues from foodstuffs. These two phases can easily be differentiated on experimental animals which have been provided surgically with antral and fundic pouches, intestinal fistulae, etc. With unoperated humans the problem of such a differentiation for purposes of clinical diagnosis is next to impossible. Hence we must treat the two as a single chemical phase, though should it ever become possible to study them separately we may find differences of great interest.

The transition from a gruel or Liebig's extract test-meal to one containing alcohol, caffeine, or other chemical substance reflects the need which has long been felt for a well-defined chemical stimulus. Because of the objections which had been raised to alcohol and caffeine, gastro-enterologists grasped at the opportunity which presented itself with the introduction of histamine into gastric physiology. Among the first to use histamine in gastric studies in humans were Cornot, Koskowsky and Libert (25); Matheson and Ammon (88); Gompertz and Vorhaus (51) and Andresen (1). Very naturally, many investigators contemplated the possibility of injecting this substance in place of using a chemical test-meal in fractional analysis. It soon became apparent, however, that histamine employed in this way could offer no distinct advantages over the usual test-meal substances (Dinkin and Wolff (33), Comfort and Osterberg (24), Gaither (45)); in fact, since histamine must be injected instead of being administered by mouth, the

acid secretory curve bears very little relation indeed to the stimulatory process arising within the stomach. On the other hand, in 1925, Gompertz and Vorhaus pointed out that a histamine injection might evoke a secretion of hydrochloric acid from individuals who gave no response whatever to the usual test-meals, and therefore it is an ideal agent for differentiating between true and false achlorhydria. Previously, in 1912, Ehrmann (36) had employed pilocarpine for this same purpose, but the violent secondary reactions from this drug made its general use impossible. Subsequently, the value of histamine in this respect was confirmed by others, e.g., Bockus and Bank (16), Dobson (34), Vandomfy (135) and Klump and Bowie (72); although Comfort and Osterberg (24) and Szmaz (132) stated that it possesses so few advantages over ordinary test-meals that its use may well be discontinued in favor of the latter (Eusterman and Balfour (39)).

It must be recognized that a chemical stimulus may be employed as a test for the responsiveness of either the glandular cells *per se*—by their direct stimulation—or of the nerve or other mechanism which ordinarily stimulates the gland cells. How alcohol and caffeine can be classified in this respect it is impossible to say at this time; histamine probably belongs to the former category. This same differentiation is implied in the clinical distinction between true and false achlorhydrias. Consequently, we believe that the histamine injection test cannot replace or be replaced by a simple chemical test-meal in a fractional series, but that they both yield information of decided value. In general, a single one-half or three-quarter hour specimen may be sufficient for the histamine test, since it is purely qualitative and acidity values have no diagnostic or physiological significance of any consequence.

We cannot leave the subject of histamine stimulation without giving some attention to dye excretion. Thirty or more years ago, Fuld (44) reported that neutral red is excreted by the gastric mucosa, following its intramuscular injection. In 1922, Finkelstein (42) showed that, of eight dyes so injected into dogs, only neutral red appeared in the stomach; that it entered through the canaliculi of the parietal cells was shown recently by Morrison, Gardner and Reeves (97). The following year Glacssner and Wittgenstein (50) reported that when the dye is injected into humans, the elimination of neutral red and the secretion of hydrochloric acid appear to run parallel, in that the time of first appearance of the dye is shorter than normal in cases of hypersecretion and longer than normal in hyposecretion; in cases of an acidity it does not appear at all. Therefore, the appearance time of the dye lends itself to a diagnostic test in the same way that histamine does.

This close parallelism could not be confirmed by Davidson, Wilcox and Haagensen (30); Winkelstein and Marcus (143); and Luria and Mogilevskii (83). Kartal (66) observed parallel behavior in only 70 per cent of the cases he studied. But, as Glaessner and Wittgenstein pointed out, these other authors employed an alcohol test-meal simultaneously with the neutral red injection, whereas they themselves studied the unstimulated stomach—hence the apparent difference in results. Since the human stomach is rarely in a complete resting state as regards hydrochloric acid secretion it would seem that the appearance time cannot be taken as a measure of secretory activity.

However, in a subsequent publication, Winkelstein and Marcus (144) reported the elimination of neutral red in all cases except the true achlorhydrias when a test-meal was given simultaneously with injection of the dyes and certain precautions recommended by Davidson (29) were taken. A similar conclusion had previously been arrived at by Davidson *et al* (30), namely, that the dye may make its appearance in the stomach even of patients with carcinoma and secondary anemia (though in small amounts), but never in cases of pernicious anemia. Its appearance in small quantities in these other instances, of course, may have been due to duodenal regurgitation, for Piersol, Bockus and Banks (106) have shown that the dye is excreted in the bile and duodenal secretion, as well as the gastric secretion of animals, and Cohen, Matzner and Gray (23) have been able to recover it from the stomach contents of pernicious anemia patients because of its excretion into the duodenum. We must conclude, therefore, that neutral red can serve no function not served by histamine, although it does not show the occasional toxic manifestations of histamine. Hence, until we know more about the physiology of neutral red excretion, we believe that it offers no signal advantage for either diagnostic or physiological purposes.

D. Volume of Secretion Versus Acidity of Gastric Contents.

In the early days of fractional analysis, abnormal cases were classified as hyper- or hypoacid. Subsequently, when physiologists had shown that the fluid secreted by the parietal cells probably always possesses approximately the same acidity, independently of pathological considerations, gastro-entcrologists realized that the variations in acidity which they observe in fractional curves are due to variations in the relative volumes of test-meal and parietal secretion as well as admixture of saliva and duodenal contents. From these considerations it follows that pathological variations in gastric secretory behavior, designated as hyper- or hyposecretory, should be evaluated in terms of the rate of secretion (i.e., the volume of secretion per time interval or per fractional specimen) rather than in terms of the acidity of the fraction.

Ordinarily it is impossible to determine the proportions of test-meal and gastric secretion in a fractional specimen, even if we assume that the volumes of saliva and intestinal fluid are negligible. However, if there be added to the original test-meal some non-absorbable substance in known concentration—some substance the concentration of which can be determined easily and with a fair degree of accuracy—the volume ratio of test-meal to gastric secretion can be calculated very easily, using the concentration of indicator substance in each of the several fractions and in the original test-meal. Such a substance we have designated elsewhere as a "dilution indicator."

The value of such a volume determination was realized well before the beginning of the present century, for in 1896, Mathieu (89) used an emulsion of oil in gum as a dilution indicator with a bread and tea test-meal. In 1910, Meunier (92) reported the use of kaolin and Laboulais and Goiffon (75) of sodium phosphate, and in 1919, Bausle (7) added $\text{Fe}_2(\text{SO}_4)_3$ to a test-meal for the same purpose. Unfortunately, all these efforts were abortive because these substances did not possess all the characteristics necessary for a reliable dilution indicator—non-absorption,

high solubility, non-reactivity with gastric contents, reliability of analytical determination, etc. Not until Gorham (52) introduced phenol red and Bloomfield and Keefer (13) introduced phenolphthalein were investigators in possession of reasonably satisfactory substances for the purpose. Although other substances have been proposed, e.g., Na_2SO_4 by Sary and Mahler (128) phenol red and phenolphthalein seem to be the only ones which have been extensively adopted by other workers. (Lewin (79), Gaither (45), Martini and Beck (87), Lanz (76), Bulger, *et al* (20) and Wilhelmj (139)). In our own laboratory we have investigated both these substances and have discovered that the use of phenolphthalein is completely invalidated by the fact that its solubility in stomach contents is much lower than its concentration in the original test-meal, and therefore most of the indicator

precipitates out within the gastric cavity (Penner, Hollander and Saltzman (103)). We are now using phenol red, for which we have developed a simple and reliable analytical procedure, in a systematic study of gastric analysis procedure to be reported on later (Hollander, Penner and Saltzman (60)). As yet, none of the results with dilution indicators reported on humans have been of significant value, for the several reasons stated above. It is questionable whether the dilution indicator method for evaluating volumes of pure secretion can ever be simplified sufficiently to be used as a routine clinical procedure. For research purposes, however, the technique contains many possibilities and the concept which underlies its use is of sufficient importance to merit its further investigation.

A Disposable Non-breakable Hard Enema Tip*

By

MANFRED KRAEMER, M.D., F.A.C.P.†
NEWARK, NEW JERSEY

SOFT rubber catheters, hard rubber and glass enema tips are in common use for administering enemas. These tips have certain common and individual disadvantages. They are all so expensive that they cannot be discarded after a single usage. They must be cleaned and sterilized each time they are used. While easy to sterilize, all are difficult to clean and even after frequent rinsings small bits of stool or barium adhere to their inner walls. The feces can be seen inside a glass tip and removed, but are often overlooked when opaque tips are used. Soft rubber tips are painful when introduced and in patients with fissures or other peri-anal lesions their introduction may be impossible. Rubber tips change in texture after several sterilizations. As manufactured, hard rubber tips are too short and the hand of the nurse becomes soiled with stool when she removes the tip from the tubing of the enema bag. For six years I have routinely used long glass tips for administering barium enemas. There is always the danger of breakage when these tips are inserted and in many hospitals their use is prohibited.

Through the co-operation of Mr. Herman Lerner of the Hygienic Tube and Container Company of Newark, I have had made a hard tip of a transparent, non-

inflammable plastic (cellulose acetate) simulating glass but unbreakable. These tips can be made so cheaply that they may be used once and discarded. I have substituted these tips for my glass ones and find them equally satisfactory. There is no fear of break-

age and subsequent trauma. Since the tips are used but once, the time consumed in cleaning and sterilizing is saved. The tips used are shown in the accompanying illustration. As the plastic is easily workable, tips can be manufactured to meet individual preferences. The tips cannot withstand boiling. If sterility is essential, they can be cleaned with soap and water and sterilized in alcohol, phenol or bichloride solutions.

Courtesy Miss Hazel Dearth, supervisor floor nurses at Presbyterian Hospital, tried the tips for routine enemas. They were time saving and economical as compared to soft rubber catheters usually employed

An Attempt To Prevent Post-Operative Jejunal Ulcer By Aluminum Hydroxide Therapy*

An Experimental Study in Mann-Williamson Dogs

By

G. B. FAULEY, M.S., M.D., A. C. IVY, Ph.D., M.D., LAWRENCE TERRY, M.S.

and

W. B. BRADLEY, Ph.D.

CHICAGO, ILLINOIS

WE have previously studied the effects of preparations of aluminum hydroxide on gastric secretion (1) by conducting controlled experiments in dogs. We observed no deleterious effects on the stomach or other organs. In view of these favorable results and the reports regarding the value of preparations of aluminum hydroxide in the therapy of "peptic ulcer" in man, it was deemed worth while to determine the effect of such preparations on the prevention of post-operative jejunal ulcer in Mann-Williamson dogs. It must be mentioned, however, that such a test of the value of any palliative remedy for "peptic" ulcer is a most rigorous one.

METHODS

Eighty-seven animals were operated according to the Mann-Williamson method except that an end-to-side instead of an end-to-end gastrojejunostomy was made. These 87 animals were divided into five groups for study. *Group I* consisted of 20 animals which were fed a limited amount of a special diet twice daily. This diet has been described previously (2). *Group II* consisted of 23 animals which given the same diet, and 10cc. of "Cremalin" hourly from xide cream (Cremaline) four times daily at 9 A. M. and at 1, 5 and 9 P. M. *Group III* consisted of 17 animals which were given the same diet and 10 grams of colloidal aluminum hydroxide powder (alucol) four times daily as in Group II. *Group IV* consisted of 13 animals which were given the same diet, and 10 cc. of "Cremalin" hourly from 8 A. M. to 8 P. M. and then at midnight. *Group V* consisted of 14 animals treated as those in Group IV except they received 3.2 grams of "Alucol" hourly and at midnight. Analysis of the acidity of the gastric contents was performed and the response to a test-meal was determined at frequent intervals.

RESULTS

Gastric Acidity. In Fig. 1 is shown the composite curves of the total and free acidity of the gastric contents in response to a test-meal before the operation and after the diagnosis of ulcer. The curves are based on an average of at least ten tests on each dog before and after operation. It is evident, as observed previously (3), that the acidity of the gastric contents of such dogs tends to be higher on the average than that of normal dogs.

In Fig. 2 is shown the effect of giving 20 cc. of "Cremalin" and of 10 grams of "Alucol" two hours after the ingestion of the test-meal. The curves represent composite results of five test-meals on each of five M-W. dogs. It is evident that the major neutrali-

zing and buffering effect of "Cremalin" is completed one hour after administration, whereas the effect of "Alucol" persists longer. This difference between the two preparations might be expected on the basis of the physical properties of the two preparations (1).

Prevention of Ulcer. The data pertaining to the prevention of ulcer are shown in Table I. The curves pertaining to the prophylactic value of the aluminum hydroxide preparations are shown in Fig. 3.

Aluminum hydroxide four times daily. It is to be noted that the average duration of life in the 20 controls, Group I, was 17.1 weeks; all died with ulcer

Fig. 1

except one (dog 20). The percentage survival time curve of this group of controls is represented by Curve A, Fig. 3. (It should be mentioned that the average survival time of 17.1 weeks is less than the 26 weeks previously reported for the special diet (2). This is due to the fact that in the previous study we gave the dogs all of the diet they would eat, whereas in this study the feedings were limited to 250 gm. twice daily because the aluminum therapy decreased appetite (vide infra). The M-W. dog does much better if he is given all the food he desires, because they suffer from intestinal indigestion).

When the aluminum preparations were given four times daily, the forty animals, Groups II and III,

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago, Ill. Submitted July 16, 1935.

survived an average of 15.5 weeks, or 1.6 weeks less than the controls. Curves B and C in Fig. 3 are the percentage survival time curves for Groups II and III.

It is evident that the aluminum hydroxide preparations, given four times daily, were of no benefit. It cannot be said that they did harm because the difference of 1.6 weeks in survival time and 4 per cent difference in loss of weight (Table I) is too small to be of statistical significance.

Aluminum hydroxide hourly and at midnight. It is clear from the curves in Fig. 2 that the aluminum hydroxide preparations were neutralizing and buffering gastric acidity only for a relatively short period of time. The data in Table II further substantiate the two conclusions drawn above in regard to the effect of the M-W. operation on gastric acidity and to the failure of a single dose of aluminum hydroxide, although relatively large, to neutralize for a long period.

Since acid is a very important, if not a prime factor, in the cause of the ulcers being studied (3), and since

we were unable to detect any real injury to the dogs resulting from the aluminum preparations, we decided to give the Al hydroxide preparations hourly from 8 A. M. to 8 P. M. and then at midnight.

By preliminary tests we found that 10 cc. of "Cremalin" or 3.2 grams of "Alucol" hourly would prevent free acid from appearing in the gastric contents. The total daily dose of "Cremalin" was 130 cc.; of "Alucol," 41.6 grams. This dosage also controlled free acidity in the M-W. dogs during the day. No aspirations were made during the night, and there is no reason to think that free acidity was under control during the night, although the midnight medication was of benefit in that regard.

On referring to Table I, it will be noted that the animals receiving Al hydroxide preparations hourly (Groups IV and V) died with ulcer sooner than the animals receiving the preparations four times daily (Groups II and III) and also than the controls (Group I). On comparing curves A, E and D in Fig. 3, it be-

Fig. 2

comes evident that the hourly administration of the Al hydroxide preparations returned the "mortality curve" toward that of the animals on the stock diet shown by curve D. Obviously the more frequent administration of the aluminum hydroxide preparations was deleterious. It annulled to a large extent, the beneficial effects of the special diet, curve A, which is also reflected by the average losses of body-weight shown by the different groups in Table 1.

DISCUSSION

In view of the relatively great effort and expense involved, the results were *very* disappointing. The results raise a new question, particularly in view of the favorable results reported clinically. Why should aluminum hydroxide have the observed deleterious action in M-W. dogs?

A consideration of this question raises the matter of the etiology of the jejunal ulcer in M-W. dogs. At

Fig. 3

least three etiological factors have been recognized, and we believe experimentally established. The first is acid irritation due to the absence of the alkaline bile and pancreatic juice. The second is the nutritional factor; these dogs have an experimentally produced intestinal indigestion; they lose considerable bile and pancreatic juice into the colon. The third is mucosal susceptibility; the jejunal mucosa is more sensitive to acid than is the duodenal. Attempts to control the acid factor in such dogs by the administration of alkalis have been of no (4, 5) or relatively little (8) benefit. Yet, when M-W. dogs are kept on a special diet and an extensive fundusectomy is performed, they do not develop ulcer (2). But, in this latter experiment the prophylactic therapy is directed both toward the acid and nutritional factors. This evidence would teach that the aluminum hydroxide therapy interferes with the nutritional factor, using the term nutritional in a broad sense. So, the question arises as to how aluminum hydroxide might disturb nutrition. The possibilities which occur to us are: (A) sufficient aluminum is absorbed to have a general toxic effect; (B) the aluminum interferes with digestion and absorption of organic food stuffs; (C) the aluminum inter-

feres with the absorption or leads to excessive excretion of certain mineral food stuffs.

A. In regard to toxicity, we have in a previous study (1) failed to find that Al hydroxide is absorbed by normal dogs. But, in M-W. dogs, there being a deficiency of alkaline secretions in the upper intestine, the Al chloride entering the intestine from the stomach is reconverted into Al hydroxide more slowly than in normal animals. This would result in more irritation of the intestinal mucosa, and might remotely be conducive to absorption of Al. Unfortunately the tissues we took from our dogs for chemical analysis for Al, were exhausted before we were successful in making a satisfactory determination. In this regard we have subjected the various chemical methods for the determination of Al in tissues to a critical analysis and as a result lost faith in all the methods except the spectrographic method as employed by McCollum, Rusk and Becker (7). We could not try this method, because we did not have a suitable spectrograph available. With their method they found no Al in tissues such as liver, kidney and spleen, or less than 0.5 parts per million. In rats subsisting for 8 months on a diet containing as much as 0.6 per cent aluminum chloride, they failed to find aluminum in the liver, kidney and spleen. We doubt that Al was absorbed from the alimentary tract of our M-W. dogs.

B. In regard to the effect of Al hydroxide on the digestion of organic food-stuffs, we (6) have found that Al hydroxide does not cause an increase in the loss of fat and nitrogen in the feces of normal dogs. No evidence was obtained on this point in our M-W. dogs. However, *one fact was very evident in our M-W. dogs receiving Al hydroxide, and that was they lost more weight than the controls and they consumed less food.* Of course, irritation of the stomach and intestine decreases appetite via the vagi. And, we have previously submitted evidence (2) showing and emphasizing the importance of a large intake (3 to 6 lbs. daily) of a diet high in nuclear substances, vitamins and readily assimilable carbohydrates for the prevention of loss of weight and for definitely delaying the onset of ulcer in M-W. dogs.

Because of the effect of the Al hydroxide on the appetite of our animals and because we could not observe at autopsy any evident irritation of the intestine we searched further for a possible explanation of the cause of the anorexia. The explanation we believe resides in the effect of Al hydroxide on phosphorus or phosphate metabolism.

C. One of the findings of Taylor (8), who was a member of the Remsen Board to investigate the effect of Alum in foods, was that compounds of aluminum decrease the phosphates in the urine and increase correspondingly the phosphates in the feces. This effect would be of little consequence unless sufficient phosphorus, as Al phosphate, were diverted into the feces to induce a relative phosphorus deficiency. One

of the earliest and most conspicuous symptoms of phosphorus deficiency is lack of appetite which leads to a loss in weight. Also, phosphorus deficient animals use less digested protein for sparing body protein than control animals. These are the predominate results of phosphorus deficiency other than the changes in the bones (9, 10).

The foregoing explanation is the most obvious and only explanation we can find for the striking loss of appetite in our M-W. dogs and for the annulment of the beneficial effects of our special diet when Al hydroxide was administered. Whether this explanation is true awaits actual experimental demonstration. The requisite experiments are now under way.

Clinically the effect of Al hydroxide preparations on appetite has not been reported. Of course, it must be kept in mind that *we used large doses* in our experiments, because such doses were requisite for the continuous control of free acidity in our animals. It must also be kept in mind that we were dealing with animals suffering a relative pancreatic insufficiency. It would appear from our work, however, that Al hydroxide therapy would be contraindicated in a patient with a peptic ulcer associated with a relative pancreatic insufficiency.

SUMMARY

Two preparations of aluminum hydroxide (an aluminum hydroxide cream and colloidal aluminum hydroxide) were given to two groups of Mann-Williamson dogs on a special diet (87 dogs were used) to determine the prophylactic value against the jejunal ulcer that results post-operatively in such dogs. The first group received relatively large doses of the Al preparations four times daily. No prophylactic value was obtained. The second group received sufficient doses of the Al preparations at hourly intervals from 8 A. M. to 8 P. M. and another dose at midnight, to control free acidity continuously during the day. No prophylactic value was obtained. In fact, the therapy proved to be deleterious. The most striking effect of the Al was to cause a decrease in appetite, a decrease in dietary intake, and a more rapid loss of weight. The cause of this is discussed and the explanation is advanced, principally as an hypothesis for future experimental testing, that the aluminum, in the presence of a relative deficiency of pancreatic juice and bile for digestive activities which these Mann-Williamson dogs suffer, combined excessively with phosphates and produced a sufficient degree of phosphorus deficiency to reduce appetite. (The most conspicuous early symptom of a phosphorus deficiency is anorexia). These experimental results would indicate that aluminum hydroxide therapy should not be employed for treating a "peptic" ulcer complicated by the presence of a relative pancreatic and biliary insufficiency, as might occur with fibrous pancreatitis or a gastro-enterostomy.

Chronic Localized Gastric Purpura*

By

RUDOLPH SCHINDLER, M.D.
CHICAGO, ILLINOIS

THE picture of the mucosa of the stomach in cases of hemorrhagic diathesis has been described similarly by all workers using the gastroscope (Schindler (24), Moutier (15), Gutzeit-Teitge (10), Henning (11)). If we gastroscopically examine a patient suffering from a purpura abdominalis Henoch, we find a pale noninflamed mucous membrane containing numerous hemorrhages of various size scattered throughout the mucosa. Emphasis has to be laid on the word "noninflamed." Inflammations of the gastric mucosa are extremely frequent, chronic nonspecific gastritis is the most frequent disease of the stomach, and its gastroscopic picture is characteristic. All easily recognizable changes are missed entirely in cases of generalized hemorrhagic diatheses. In them only noninflammatory hemorrhages are found, lying in the intact gastric mucosa as they are found to lie in the non-inflamed skin.

However, this picture is not characteristic of a general hemorrhagic diathesis. It also has been observed without a generalized tendency to bleed, merely as a *localized disease of the stomach*. This disease, and its typical development has been emphasized repeatedly (21). Later P. Chevallier and Moutier (5) made the same observation. They used the name: "Purpura chronique isolé de l'estomac." Although this expression may cause confusion because it may suggest some close relation with the well known disease of the skin which definitely does not exist, I am inclined to accept this name provisionally.

It seems to me that the "chronic isolated purpura of the stomach" is not only a new, but also an important disease. It has a definite gastroscopic and clinical picture. Gastroscopically, besides the already mentioned more or less numerous mucosal hemorrhages, dark brown round or star-shaped spots may be found. They are usually 2-5 mm. in diameter, but occasionally much larger. They apparently develop from the mucosal hemorrhages; the transition may be observed if the patient is gastroscopied at frequent intervals. Hemorrhages and pigment spots may be found along the anterior and posterior wall, but are most frequently in rows along the lesser curvature. The common site of their location is a point about 3 cms. above the angulus. The pigment spots disappear slowly, probably by absorption. However, some hemorrhages, instead of being absorbed, become ulcerated and develop into a hemorrhagic erosion, red, grayish-red or brownish-red in color. Gastroscopy has verified the observation of older pathologists: that true hemorrhagic erosions do exist. By the fact that they may become ulcerated, the eruptions of the localized purpura of the stomach are definitely different from the skin-eruptions in generalized purpura. However, it is easy to explain this difference. In the stomach the acid gastric juice developing peptic power is present;

it is more than likely that the gastric wall may lose its autoprotective power against autodigestion if it is damaged over a too long period of time by some disturbance of the circulation. The frequent coincidence of such isolated gastric purpura with true gastro-duodenal ulcer does not prove that hemorrhagic erosion is the acute stage of chronic gastro-duodenal ulcer. Chronic inflammation also often is observed in stomachs containing true gastro-duodenal ulcer, and nevertheless I believe that the inflammation is secondary to the ulcer. However, it would not be easy to explain the presence of noninflammatory gastric hemorrhages by assuming that they are effected by the ulcer; it would be very difficult to explain why they so often are found at the place of predilection of ulcers, namely at the angulus; and finally, I believe I have observed the transition of mucosal gastric hemorrhages into true gastric ulcer.

Therefore, I believe that—

1. there is a definite relationship between chronic localized gastric purpura and chronic gastro-duodenal ulcer,—that
2. chronic isolated gastric purpura may precede or follow chronic gastro-duodenal ulcer or they may be found together,—and that
3. the hemorrhagic erosion, having its origin from the chronic isolated gastric purpura by the peptic quality of the gastric contents, may be the acute stage of chronic gastro-duodenal ulcer.

CASE HISTORIES

Some abbreviated case histories may give an idea of the clinical picture of chronic isolated gastric purpura and its consequences.

(a) Mucosal hemorrhages in normal mucosa.

Case 1. A girl, twenty years of age, had suffered from epigastric distress for three years. The pain was of the ulcer type, delayed, periodic. Gastric analysis revealed free acidity of 56, total acidity of 75. Free HCl also was found in the fasting stomach. No occult blood was found in the feces. Repeated X-ray examinations failed to reveal any abnormality. Since most refined repeated examinations did not discover any disease she was treated for years as a psychoneurotic. Finally gastroscopy revealed two marked hemorrhagic spots above the angulus in the lesser curvature, i. e. at the common ulcer site. After a period of careful ulcer management the distress disappeared completely, and at the time of the last report several years later it had not returned.

(b) Mucosal hemorrhages, pigment spots and hemorrhagic erosions in a case of severe gross hemorrhages.

Case 2. A white woman, fifty-six years of age, had had several gross hemorrhages during the past years. X-ray examination with the compression technic did not reveal any evidence of gastric disease; at gastroscopy the entire stomach was well seen; the activity of the pylorus was normal. In the greater curvature of the antrum there were two round pigment spots. In the lower part of the body almost all the folds contained mucosal hemorrhages and pigment spots, without any sign of inflammation. In

*From the Medical Department of the University of Chicago.
Submitted July 25, 1933.

the anterior wall two definite superficial erosions were seen, surrounded by a hemorrhagic area; one of the erosions was yellowish-gray in color, the other brilliant white. Below the cardia extensive hemorrhagic areas were observed without inflammation. The mucosa appeared pale. The gastroscopic impression was:

1. numerous mucosal hemorrhages of various sizes
2. multiple pigment spots
3. two hemorrhagic erosions.

Two days later the patient had again a severe but not fatal gross hemorrhage.

Hemorrhagic noninflammatory erosions as the source of gross gastric hemorrhages are not very rare. I have observed three such cases.

- (c) Hemorrhages, pigment spots and gastric ulcer.

Case 3. A thirty-three year old female complained of epigastric distress. The physical examination was negative. The Ewald test of gastric secretion disclosed a free acidity of 52, a total of 70. The benzidine test of occult blood in the stools was negative. An X-ray examination of the stomach was negative. Gastroscopy: The lesser curvature was covered with star-like and streak-like small pigment figures; in some places, especially in the posterior wall there were fresh mucosal hemorrhages. In the anterior wall, below a fold in which three pigment spots were seen, there was a round ulcer with quite a sharp edge about 1½ cm. in diameter, its floor yellowish, its edge toward the pylorus, pigmented, toward the cardia, hemorrhagic. Otherwise the mucous membrane was normal. This ulcer had apparently developed in a hemorrhage which already had partly changed into pigment.

- (d) Mucosal hemorrhages and duodenal ulcer.

Case 4. A forty-three year old female had complained of epigastric distress of the ulcer type for eight years. Gastric analysis revealed a free acidity of 20 and a total of 52. X-ray disclosed a frank deformity of the duodenum, typical of duodenal ulcer. At gastroscopy no gastric changes were noted, except that there were many discrete and linear-shaped mucosal hemorrhages and pigment spots on a fold of the lesser curvature.

- (e) Mucosal hemorrhages after ulcer.

Case 5. A thirty-two year old female complained of pain in the epigastrium, belching, and heart-burn. X-ray examination disclosed a duodenal ulcer with a moderate stenosis. Operation (Dr. Dragstedt): small puckered scar on the anterior wall of the duodenum. Incision was made through the pylorus and extended into the duodenum and stomach. An ulcer about 1½ cm. in diameter was found on the posterior wall of the duodenum. A pyloroplasty was performed. Four years later the symptoms recurred. Gastroscopy on May 2, 1935, showed a gastric ulcer without inflammation. Ulcer management was resumed. Gastroscopy on July 16, 1935: the site of the ulcer previously seen was somewhat elevated and scar-like. On the lesser curvature just above the angulus were many small mucosal hemorrhages. Similar hemorrhages were present on the lowest part of the posterior wall.

The incidence of localized gastric purpura after the healing of gastric ulcer is so frequent that numerous respective case histories could be quoted.

- (f) Hemorrhagic erosion after ulcer.

Case 6. A forty-five year old male complained of abdominal pain and vomiting of two months' duration. The pain was left-sided, not related to food. Slight tenderness was present in the epigastrium. X-ray reported an enormous dissecting ulcer on the lesser curvature of the stomach. Gastric analysis revealed a free acidity of 72. The benzidine test for occult blood in the stool was strongly positive. Six months later X-ray reported complete healing of the ulcer. Gastroscopic examination reported the action of the pylorus to be normal. No ulcer or scar was found anywhere along the lesser curvature. Near the lesser curvature above the angulus in the anterior wall there were some hemorrhages, in one of which

was seen a flat but definite erosion with an extremely red edge. All other parts of the stomach were quite normal. Diagnosis: Typical hemorrhagic erosion. The patient at this time was feeling fine. One year later gastroscopy reported the following: At the point where the smooth musculus sphincter antri touched the lesser curvature there were mucosal hemorrhages. Other streaky and spotty hemorrhages were seen in the mucosa of the lesser curvature and the posterior wall. A single small hemorrhage was seen on the greater curvature. The hemorrhagic erosion had healed. Diagnosis: Healed hemorrhagic erosion. Numerous hemorrhages were in the normal mucosal membrane.

It thus becomes evident that, although hemorrhagic erosions and even large ulcers may heal, the stomach still retains the characteristics which I interpret as those of the "ulcer" stomach, namely it presents the picture of a localized gastric purpura.

- (g) Bleeding hemorrhagic erosion, hemorrhages, pigment spots and duodenal ulcer.

Case 7. A forty-five year old male complained of gnawing epigastric pains one-half to two hours after meals. A physical examination was negative. The benzidine test revealed a trace of occult blood in the stools. The histamine test of gastric secretion revealed a free acidity of 32. Roentgenologically a deformity of the duodenal bulb characteristic of duodenal ulcer was reported. Gastroscopy reported the whole stomach to be seen. The pylorus was round and widely open without contraction. The anterior wall of the upper region contained many large hemorrhages, pigment spots, and in some places small, hemorrhagic erosions. One of the latter was freshly bleeding into the cavity of the stomach. Radial folds were converging toward this point. The aspect of the contiguous mucous membrane was normal.

In this case the bleeding of a hemorrhagic erosion was actually seen.

DISCUSSION

These case histories show that chronic localized gastric purpura often presents clinically the picture of an ulcer though no ulcer is present. The mucosal hemorrhages are transformed into pigment spots, then absorbed. Sometimes hemorrhagic erosions develop in them, eventually severe gross hemorrhages may occur. The formation of true chronic ulcer from these acute hemorrhagic erosions is likely. Chronic localized gastric purpura is often found together with a chronic gastric or duodenal ulcer, or may be found before the development of such an ulcer or after its healing in 44 per cent of all cases observed. Not infrequently chronic localized purpura is observed over a long period of time without an ulcer developing. This uncomplicated chronic localized gastric purpura is observed in 5.6 per cent of all patients examined gastroscopically.

PATHOGENESIS

The question of the pathogenesis of this almost unknown disease leads to the most interesting statements. Almost all research work done on the great problem of the hemorrhagic diatheses has considered exclusively blood and blood vessels. The American school in the beginning had different conceptions to be mentioned later, but finally the influence of the German school prevailed, and more or less the conceptions of Frank (7), Glanzmann (8), etc., were adopted. Glanzmann subdivided purpura in the two great groups of anaphylactoid and thrombopenic purpura, but already Morawitz (14) recognized that reduction in the number of the thrombocytes is a subordinate finding.

It is not possible to consider general disturbances to be the cause of *localized* gastric purpura. If the blood were diseased, why should such a blood disease cause extravasations only in the area of the stomach, or why should the vessel walls be altered only in this area? This is not yet understood. Therefore, the observation of chronic localized gastric purpura leads us back to older opinions of American authors who believe that the *nervous system* has the decisive role in producing hemorrhagic diatheses. Probably the first man to advance this opinion was *Weir Mitchell* (13). He wrote on "Purpura as a neurosis." He described neuralgias accompanied by muscular spasms in which at the place of the most outspoken pain regularly ecchymoses developed. He observed furthermore cases of purpura in which accompanying pains and symmetrical distribution of the eruptions led him to the diagnosis of a neurosis. He asked whether certain conditions of the nervous system would be able to weaken the walls of the blood vessels so that they become permeable for the red blood cells. Better proofs for the primary affection of the nervous system in hemorrhagic diatheses were presented by *Castex* (3, 1) anatomically, and by *Schindler* (22) clinically.

Castex was the first (the paper of *Gordon* (9) is not convincing) to demonstrate definite histological changes of the central nervous system in two cases of symmetrical purpura. He found severe changes of the cells of both lateral superior nuclei of the sympathicus, reduction of the number of cells, diminution of the still existing cells, retraction of the cell body, central chromatolysis with accumulation of the granulations at the periphery, diminution of the number of the dendrites, briefly all those changes which are found in cell sclerosis.

These findings concerned the spinal centre. *Schindler*, however, believed that purpura-eruptions may occur if any part of the vasomotor tract is diseased. He observed noninflammatory purpuric skin eruptions in neuritis, tabes, combined cord degeneration, multiple sclerosis, lethargic encephalitis, hemiplegia, and in one case of brain tumor in the skin only of the paralytic extremity.

Is destruction or alteration of the nervous centres known in cases of localized hemorrhages of the gastric mucosa? Experimental research has provided us with ample material to prove that lesions of the hypothalamus may cause hemorrhages of the gastric mucosa and superficial hemorrhagic erosions.

The first research in this subject was carried out by *Schiff* (19) as soon as 1867. *Brown-Sequard* (1) in 1876 wrote on alterations of the gastric mucosa following cerebral lesions. However, a new interest in this connection arose following the *Balfour* lecture of *Cushing* (6) in 1932 who believed in a connection between hypothalamic disturbance and certain gastro-intestinal lesions. *Burdenko* and *Mojilnitski* (2) produced small lesions in the base of the brain which resulted in gastric hemorrhages and erosions, acute ulceration and occasionally perforation with peritonitis. They assumed destruction of a vasomotor centre in the posterior hypothalamus and of a metabolic centre in the tubular region. *Watts* and *Fulton* (25) worked on the effect of lesions of the hypothalamus upon the gastro-intestinal tract and heart in monkeys.

Multiple erosions of the stomach were encountered after hypothalamic injury. They occurred most frequently in the body of the stomach. Of seventeen animals with large hypothalamic lesions, four developed gastric erosions, one died of a *perforated duodenal ulcer* and frequently mucosal hemorrhages were found. In the control series erosions were found only in one monkey who had had a midthoracic resection of the spinal cord. Other spinal or cerebral lesions did not lead to erosions. *Hoff* and *Sheehan* (12) also experimented on monkeys. Following hypothalamic injury five animals of sixteen showed *multiple hemorrhagic erosions* in the mucosa of the body of the stomach.

With these experiments a definite connection between lesions of the hypothalamus and the development of mucosal gastric hemorrhages and hemorrhagic erosions of the stomach is established. Some connection between such lesions, gastric mucosal hemorrhages and erosions, i. e. chronic isolated gastric purpura, and true gastric ulcer seems to be likely at least.

How is it possible to explain extravasation of blood following lesion of the vasomotor tract, resp. of the hypothalamus? The theory of spontaneous hemorrhages has been advanced decisively by *Natus* (17). He experimented on the duodenal coil and the pancreas of rabbits and came to the conclusion that protracted irritation of the vasomotor nerves leads to complete interruption of the relation between nervous system and wall of the blood vessel. He found that the irritability of the vasodilators disappeared and finally stasis occurred, although the activity of the heart was not impaired. When this stasis developed slowly *extravasation of red blood cells* from the capillaries was seen. The blood stasis in a portion of the capillaries caused resistance resulting in increased side-pressure in the neighboring still working capillaries, and this increased side-pressure expressed the blood into the tissue. Therefore it may be assumed that lesion of the vasomotor tracts of the gastric nerves leads to stasis in the capillaries and subsequent mucosal hemorrhages. It is possible that vagus stimulation leads to continuous production of acetylcholine, and that this production of acetylcholine causes diminished blood flow through the stomach, as described by *Necheles* (18), with stasis and extravasation of blood. Therefore it is easy to understand that lesions of the hypothalamus may lead to gastric purpura. The gastric peptic juice then may erode the weakened gastric wall causing hemorrhagic erosions. And it is easy to understand that, if the nervous irritation lasts too long, chronic ulcer can develop.

CONCLUSIONS

1. The clinical and gastroscopic picture of chronic isolated gastric purpura is described and illustrated by case histories. Its relation to mucosal pigment spots, gastric hemorrhagic erosions, and chronic gastro-duodenal ulcer is discussed.

2. An attempt is made to explain the pathogenesis of this disease—according to *Castex*'s conception—by assuming lesions of the nervous system. The mechanism of lesions of the vasomotor tract leading to spontaneous blood extravasation is described.

A Review of Some Foreign Literature

By

RUDOLF SCHINDLER, M.D.*

CHICAGO, ILLINOIS

1. GERMAN

ASCHOFF (1) published a series of articles on the anatomy of senility. These short but exhaustive descriptions may become classic. Here the article on the "digestive tract in senility" is of special interest. The expression "senility" refers to the ninth and tenth decade of human life. Because of the loss of elastic tissue the entire alimentary tract becomes longer in senility. The mouth presents loss of the teeth, atrophy of the jaw, prominence of the chin. (The order in the loss of teeth is a definite one, the premolars being the first, the canini the last to be lost. In the tonsils regressive processes are observed; true angina is very rare in senility). The tongue shows senile atrophy of the voluntary musculature, the mucosa is thinned, but patchy leukoplakias are also found. However, carcinoma of the lip may be found without preceding leukoplakia. It is found only in men and probably is due to irritation by the tar-containing juice of pipes. In the esophagus leukoplakia is found. The lower end of the esophagus becomes more movable than it was before, and that may lead to the formation of hiatus hernia. The stomach shows often a marked thinning of the mucosa, the system of folds disappears, the glands of the corpus are replaced by pyloric duodenal glands. This happens especially along the "Magenstrasse."

Slowly the area of the acid secreting mucosa is diminished. This may be a reason why in senility fresh ulcerative lesions are rare. Ulcer-Cancer is not characteristic in old age, but other forms of cancer occur in the atrophic gastric mucosa, produced by the attempts of the epithelium to regenerate. The shape and position of the stomach are changed, a horizontal position being frequent. The intestine becomes more and more immune to bacterial attacks. Typhoid and dysentery are almost unknown in old age. Carcinoma is more frequent in old age than in senility. Appendicitis is very rare, but diverticulosis and diverticulitis are frequent. The salivary glands show atrophy. Their

cylindrical epithelium changes into squamous epithelium. Therefore, staphylococci infections are frequent. Cirrhosis of the pancreas is not a disease of senility. Its fat hypertrophies to replace the glandular tissue. The number of oncocytes (special cells stained yellow with Sudan III) increases. The chief disease of the liver in senility is not cirrhosis but brown atrophy. The lobules are diminished in number, brown, their centres being reddened. Microscopically accumulation of lipofuscin is seen in the small liver cells. No senile changes of the biliary ducts occur.

The relation of *vitamines* to diseases of the alimentary tract is now of much interest. Einhauser (2) believes that hypovitaminic conditions are more frequent than avitaminoses. In cases of C-vitamine-deficiency, inflammation of the alimentary tract is frequent. He quotes Eusterman's opinion on the importance of Vitamins C in the healing process of gastric ulcer and Thiele's observation that gastric hemorrhages are frequent especially when a scarcity of Vitamins C-containing food exists. Vitamin C-deficiency may be caused by insufficient absorption in the gastro-intestinal tract. Patients with anacidity did show increase of the reduction-value in the urine when ascorbic acid was injected, but failed to show this phenomenon when the ascorbic acid was given by mouth. However, when the ascorbic acid was given in an "acid milieu" by adding lemon juice, sufficient absorption took place.

The discovery of the frequency and importance of chronic nonspecific gastritis has brought out a great many questions, especially as far as definition and classification are concerned. Every paper from Katsch's clinic has to be considered carefully because Katsch was one of the first men to discuss and advance these complex problems (see his chapter on Chronic gastritis in Bergmann-Staehelin, *Handbuch der inneren Medizin*, Berlin, 1926 Springer, III. Bd. 1. Teil, p. 554). He has recently described two new types of gastritis: the mucoid and the serous gastritis. Now, Baltzer (3) undertakes to describe the methods of

*University of Chicago.
Submitted July 4, 1935.

recognition and to discuss their value in diagnosis. He claims that always three different adjectives should be added to the diagnosis of gastritis: the first indicating the clinical picture, the second indicating the function, and the third one indicating the specific anatomic lesion, as for instance: "Gastritis acuta dolorosa, superacida mucosa, polyposa of the body." Such a concept cannot be easily accepted. The re-introduction of the diagnosis "gastritis" presupposes our knowledge that definite anatomic inflammatory changes of the stomach exist, and that compared with these anatomic pictures clinical symptoms as well as function are relatively meaningless. This consequence will be drawn easily from the extensive and critical research work of Baltzer himself. He emphasized that in cases with increased mucus of the gastric juice usually no gastric disease is found, but that an "instability of the whole organism" exists. There is no objection to add adjectives denoting one or several partial functions to the anatomic diagnosis of gastritis, but first one must know whether or not there is an anatomic substrate for subjective symptoms and alterations of function. The paper of Baltzer describes the methods of measuring albumin and mucus in the gastric contents, and gives a clinical survey.

The papers read at the Second International Congress of Gastro-Enterology in 1937 (4) have now been published and many of the papers are of interest. The discussion on the early diagnosis of gastric carcinoma brought out important contributions. Kapp's statistics are of special interest (p. 592). Gastric distress was found to have been present for 7.3 years in the average of 39 cases of carcinoma of the corpus, for 2.4 years in 66 cases of pyloric carcinoma and for 0.33 years in 15 cases of carcinoma of the cardia. Sometimes the story was brief, in other instances long, up to 30 years. In a large group of cases indefinite symptoms such as epigastric pressure, fullness, weakness, belching, lack of appetite were present for a long time and usually were considered to be the symptoms of a psychoneurosis. Gastroscopists know that these symptoms are very suggestive of chronic atrophic gastritis. Therefore, one group of gastric carcinoma probably develops from atrophic gastritis. This has been proved also by histologic examinations. According to the histories in 12 of 66 cases of pyloric carcinoma and in 24 of 39 cases of body carcinoma gastritis probably preceded the development of the carcinoma.

Therefore Kapp also checked over 157 cases of gastritis observed at the Basel University Clinic. Five years or more later 21 of these cases or 13.4% were treated because of gastric cancer. The average time elapsed between the making of the diagnosis of chronic gastritis and the finding of a carcinoma 12.5 years. Similar observations were made by Uslan who, in 125 cases of gastritis, found that gastric carcinoma developed in eighteen. In one-seventh to one-eighth of

all patients suffering from chronic gastritis, gastric carcinoma develops. Kapp believes that we need periodic checks of all patients suffering from chronic gastritis in order to come to an early diagnosis of gastric carcinoma. This opinion is shared by Katsch (p. 372) who claims that much of the money and effort spent on cancer research should be used in research on chronic gastritis.

2. THE DUTCH LITERATURE

It is interesting that a book on gastroscopy has now been written in the Dutch language. Bloem's (5) monograph though based on a limited number of personal observations, is very satisfactory. Of special value is his thorough knowledge of the literature and his exhaustive description of the development of gastroscopy.

3. THE FRENCH LITERATURE

The relation between diseases of the stomach and the blood will be the chief topic of the next international gastro-enterologic congress. An exhaustive study has been made by P. Chevallier and Fr. Moutier (6). The mucosal changes occurring in pernicious anemia, chlorosis, secondary anemias of different kind, and in purpuras have been observed gastroscopically in numerous cases. Four colored plates show the generalized atrophies, the "nacreous patches" found in pernicious anemia, and the noninflammatory hemorrhagic phenomena of the gastric mucosa (localized autonomous gastric purpura). Moutier and Debray (7) describe the pathology of the "juxta-pyloric" region of the stomach. Congenital diverticula, spasms, ulcers, tumors of this region are described and pictured.

Moutier (8) contends that the stomach resembles the skin in that there are some definite types of inflammation, but besides them a great number atypical lesions which do not belong to any definite type and haven't any definite symptomatology. He describes the "Gastrite boutonneuse" (pustular gastritis) as belonging to this group. He observed in five patients pustular, whitish, stump-like lesions, seen together with some type of gastritis, but disappearing after a short time. Although the presence of these lesions cannot be denied it remains questionable whether it is wise to give them a name of their own. Evidently they may be seen in edematous, atrophic and other forms of gastritis. However, the observation is a very interesting one. In Beaumont's classical description of gastritis changes occurring in Alexis St. Martin's stomach, there was only one lesion which 100 years later was not seen at gastroscopy, namely that of vesicles. Moutier's observation of whitish pustules recalls to our mind Beaumont's description of vesicles. Perhaps Beaumont has been correct even in this last point.

Problems of Maintaining Nutrition in the Highly Food-Sensitive Person*

By

WALTER C. ALVAREZ, M.D.†

ROCHESTER, MINNESOTA

DURING the last few years medicine has been passing through a stage in which any one of us physicians does well if, in a given case, he suspects that the symptoms complained of are due to marked food-sensitiveness, if he succeeds in identifying the offending foods, and if by removing them from the diet he works a cure. These are no mean accomplishments, but the time has come when we must not rest satisfied with them but must demand of ourselves another, namely, that of replacing the hurtful foods taken away with enough harmless ones so that the patient can remain well nourished and contented. Unfortunately, as yet, most of us seem to be mainly concerned with the *taking away* of foods, and as a result, we are beginning to see a certain number of emaciated men and women whose plight is due to too long an adherence to some highly restricted and inadequate type of diet.

MAINTAINING NUTRITION IS SOMETIMES DIFFICULT

Sometimes one cannot blame anyone for this situation because the problem of maintaining good nutrition in an adult or child who begins to wheeze or sneeze or bloat within a few hours after eating even small amounts of such commonly used and important foods as wheat, milk, eggs and beef, must obviously be difficult. I have under my care a woman who, when I first saw her, could live in comfort on only two foods. At first almost every effort I made to find something new for her resulted in a bad digestive upset with pain, diarrhea, loss of sleep, and loss of weight, and only after much searching did I find a number of foods that she could eat with comfort. Curiously, when these were found, all sorts of bizarre symptoms left; she began to gain in weight, and her bowels moved normally.

THE NEED FOR TAKING FOODS IN ROTATION

Naturally, unfortunate people like this must soon become bored with their narrow diet. Also because they eat so much of the few foods that they can take and eat them so often, they are likely soon to be sensitized to them, and thrown back onto starvation rations.

Some time ago a patient like this, who was almost at the end of her rope and facing starvation, solved the problem by taking in rotation the foods to which she was only slightly sensitive. As all allergists know, there are many persons who can take a small amount of a harmful food at intervals without serious trouble, but if they are to eat larger amounts or particularly if they eat the food every day for several days, they get into serious trouble. The trick then is to eat each mildly harmful food once a week or so, so that its effects will not become cumulative.

The trouble is not in their heads. Some physicians

and dietitians suspect that in these cases the trouble is "in the patient's head," but it isn't. It is in some fussy persons with many prejudices and dislikes, but an expert can soon distinguish these persons by their behavior and their answers to searching questions.

One of the most useful features about an elimination diet is that it exposes the overly fussy, the psychopathic, the unreasonable and the stupid patient within twenty-four hours, and shows how hopeless it is in the particular case ever to fit *any* diet that will work.

One of the best proofs that the troubles of a patient are not due to imagination but to specific food-sensitiveness is that he gets sick when the offending food was so well concealed in some harmless looking dish that he had no suspicion that he ate it. Thus, a friend of mine who is highly sensitive to oysters, almost lost his life one night through eating a few mouthfuls of duck which he would never have touched if he had suspected that the dressing contained a few chopped oysters. Within a few minutes after eating the duck, the man was lying on the floor, unable to breathe, black in the face, and almost unconscious. He had forewarned his host of his idiosyncrasy, but the cook had no patience with "such foolishness" and in went the oysters anyway.

Another of my friends dreads dining out because of his great sensitiveness to cottonseed oil. He thought he had learned to avoid all foods that might possibly contain this oil, but recently he came to grief in a curious way. When, after a quiet dinner at home, the typical retching started, the only food that could possibly be looked on with any suspicion was some dates; but how could these have come in contact with cottonseed oil? The mystery was solved next day when the grocer explained that since people like their dates shiny, he wipes off the top ones in the box with an oil-soaked cloth!

Another patient who is highly sensitive to chicken will, in spite of every care, occasionally fall ill with the syndrome which he knows all too well. Inquiry then reveals the fact that an innocent looking cream soup eaten four hours before happened to have been made with chicken broth instead of beef stock.

The need for the proper labeling of foods. I might go on telling many interesting stories of this type, all showing, first, that these allergic people are not imagining their troubles, and second, that it is highly desirable that they be given information as to the composition of the foods that are set before them or that they buy from the grocer. Obviously, it would be helpful to them if the purveyors of foods would list on the label all of the materials that go into a particular can or bottle or package.

Here, for instance, is a woman to whom any trace of a corn product is poison. How can she know as she eats some canned fruit, jelly, candy, mayonnaise, "olive oil," sardines, or bakery product that she is not

*Read before the meeting of the American Public Health Association, Section on Food and Nutrition, New York, October 6, 1937.
†Division of Medicine, The Mayo Clinic, Rochester, Minn.
Submitted July 1, 1938.

going to ingest some corn sugar, corn oil, or corn starch? Here, too, is the mother of an asthmatic child who wheezes and snuffles all night if a little wheat, milk, or egg gets into his food. When she buys him some arrowroot cookies how can she tell if there is any trace of the offending foods in them?

"Arrowroot" may be many things. But even if she could find this information on the label this might not solve her problem. It is conceivable that the child might be insensitive to the common "arrowroot" made from the West Indian Maranta, but sensitive to the Tous-les-mois or Queensland variety made from a species of Canna, or to the East Indian arrowroot made from a species of Cureuma, or to the Brazilian arrowroot made from cassava, or to the Tacca arrowroot made from the pia plant of Tahiti, or to the Portland arrowroot made from an Arum. A child highly sensitive to potato would be made ill also whenever the food manufacturer let himself be cheated into buying arrowroot highly adulterated with cheap potato starch.

This paragraph on arrowroot alone should show what a difficult situation the allergic person is now up against when he tries to avoid eating one or more foods to which he is highly sensitive.

The Food and Drug Act does not help. I understand that the Food and Drug Administration has urged Congress to help markedly allergic persons by revising the law so as to require manufacturers to list on their labels the several constituents of foods, but the proposal has been fought by men who fear either to give away trade secrets or to run up against certain prejudices of housewives.

Food packers may help voluntarily. It may be that some day such labeling will be compulsory, but what I think will happen first is that some of the packers will find that it pays to cater to the needs of the group of highly food-sensitive persons, just as it pays now to supply mothers of delicate children with finely puréed and comminuted vegetables of all kinds, and I presume it pays to supply diabetics with special breadstuffs and fruits which are canned without syrup.

Especially if the allergists of the country were to help in disseminating information about the properly labeled foods, a good business might soon be developed. A hopeful point for the manufacturer would be that the potential market seems constantly to be increasing. Either we physicians are coming to recognize allergic troubles more often or else the percentage of allergically sensitive persons in the community must be increasing rapidly.

It is hard to estimate the number of highly food-sensitive persons in this country, but one can get some idea of how many there are among persons with indigestion. When Hinshaw and I questioned 500 patients we found almost everyone had to avoid one or two foods. Twenty-six per cent were sensitive in some degree to milk, 18 per cent were sensitive to chocolate, and 13 per cent were sensitive to eggs. But when we made a list of the persons made *severely ill* by eating foods we found 7 per cent (of the 500) sensitive to milk, 5 per cent sensitive to chocolate, 4 per cent to apples, 3 per cent each to eggs and tomatoes, and 2 per cent each to cabbage, meat, corn, coffee and bananas.

Vaughan, in his survey of 500 villagers in Virginia, and Hughes, in her study of 1,000 avowedly healthy persons, each found about 60 per cent who were food-

sensitive. Rowe found 31 per cent food-sensitive among 400 university students and nurses. The percentage arrived at in any such canvass will depend on the care and pertinacity used in the questioning.

The need for special bakeries. Already Rowe has found it necessary to get a baker to supply some of his allergic patients with wheat-free breadstuffs made of only one or two starches obtained from such sources as rice, rye, potato, barley and the soy bean, and doubtless more such bakeries will some day be opened.

THE USE OF FOODS NOT ORDINARILY USED IN AMERICA

Allergists will doubtless soon be reaching out to the ends of the earth to secure new foods which, if our original theories were correct, should never cause the American patient trouble because he has never eaten them and therefore has not had an opportunity to become sensitized to them. Although this securing of new foods is helpful, it does not solve all our problems because there are some persons so sensitive as to react violently to many a food which, so far as can be determined, is new in their experience.

According to Vaughan, the reason for this is found sometimes in the close botanic or biologic relationship of the new food to some old one to which the person is sensitive. Thus a man who is sensitive to orange juice is likely to be sensitive to grapefruit juice, but he doesn't have to be. Sometimes the sensitiveness is specific, as in one of my friends who is highly sensitive to chicken, domestic duck and goose, but not to turkey, pheasant, guinea hen, squab or wild duck.

Although, then, a new food never eaten before may prove injurious to a highly allergic person, the physician can sometimes work a miracle for some poor half-starved person by reaching out to Asia or Africa for new articles of diet. Thus, one of my patients, who had starved down to 89 pounds, was given a new lease of life when in some food stores patronized by immigrants she found such foods as dried Lichi nuts and chestnut flour from China, garbanzos and favas from Spain, papaya syrup from Florida, taro flour from Hawaii, and soy beans from Manchuria.

Beans and peas. The garbanzo or chick-pea makes a tasty and highly nutritious dish. A fine big white bean is the Spanish fava. Unfortunately, a few persons are highly sensitive to it. The soy bean is full of nutriment and recently a way has been found of removing its unpleasant taste. Rowe uses flour made from the lima bean.

Taro. Taro is a big mealy tuber which is one of the most prized foods of the Polynesians. It is now being packed in Hawaii either as a fermented paste or as a powder suitable for the making of mush. This tuber is tasty and highly digestible, and so different botanically from any American food that it should be acceptable to many highly allergic patients.

Breadfruit and bananas. Something might also be done with flour made from the breadfruit, another Polynesian standby. Flour might be made also from dried bananas, and if it should happen to retain some of the glutinous properties of the fresh fruit, it might be useful as a binder to help the baker in making breads without wheat. Much experimenting needs to be done along these lines. The banana can, of course, be used either raw, or better still, cooked.

Rice and barley. Rice, which is the principal food of millions of Asiatics, is one of the best foods that

the allergically-sensitive person can try. Few are unable to digest it comfortably.

Next to wheat, the grain most commonly used in the world is barley. Three species and several subspecies are cultivated. The flour is not glutinous enough for bread-making, and hence through the ages, the grain has been used mainly for the production of beer. Robinson's barley flour makes a delicious breakfast food, and as every cook knows, pearl barley is a good thickener for broths.

Oats and rye. Other flours which are useful sometimes as substitutes for wheat are oats and rye. As yet patients have trouble either in getting these made up into bakery products in pure form, or in eating them as breakfast food without milk or cream. The well-known "rye Krisp" can be of help to the wheat-sensitive person. Robinson's Scotch groats is a very fine, easily digested form of oatmeal.

Millet. Flour made from millet might be tried in the feeding of allergic persons. It was probably the first grain to be used by man, and it still is regarded as an important source of food by primitive peoples in many parts of the world.

Buckwheat, maize, etc. Buckwheat might also be used, as it is not at all related to wheat or to the other commonly used grains. It came originally from the foothills of the Himalayas.

Maize or American corn is an excellent source of carbohydrate and fat, but unfortunately at least one in seventy otherwise normal persons is highly sensitive to it (Hughes), and one in fourteen dyspeptics has some trouble with it (Alvarez and Hinshaw).

An often harmless variety of starch can be obtained from various types of peas and lentils and from the chestnut.

Cassava. Cassava is an important source of food in West Africa, South America, and in several other parts of the world. There are two main varieties, the bitter and the sweet. The white starchy pulp is obtained from large tuberous roots. In commerce cassava starch is sold under the names of "tapioca" or "Brazilian arrowroot." It may well prove useful in the feeding of allergic persons.

Sago. Sago is prepared from the trunks of several species of palms, most of them growing in the East Indies. A form of sago is made also from the pith of a species of Cycas, and all of the varieties are sometimes adulterated with potato starch.

The difficulty in using sago and some of the other starches in elimination diets lies in the fact that cooks are not used to preparing them without adding milk and egg. I find I can give them in apple sauce. Although raw apples are very common producers of indigestion, the cooked apple seems seldom to cause trouble. These starches go well also in mutton broth or lamb stew.

Maple sugar. I sometimes use maple sugar for a day or two as an elimination diet. Few persons should be sensitive to it allergically, but some feel discomfort if they take any considerable amount of any kind of sugar. Possibly when given in concentrated form, it acts as a physical irritant, dehydrating and thereby irritating the gastric mucosa.

Fats. Persons who do not tolerate butter or the now commonly used corn and cottonseed oils and the hydro-

genated fats made from them might experiment with oils obtained from the olive, coconut, peanut, or soy bean, or from sesame or rape seeds. Care would have to be taken to secure these oils unadulterated and untreated with dyes and other substances.

A fine vegetable fat is to be found in the avocado or alligator pear, a fruit which is now becoming cheaper every year as more and more trees come into bearing in the more tropical parts of this country.

Substitutes for breakfast fruit. For those persons who cannot touch citrus fruits or melons, the papaya may come to serve as a substitute. It is not at all related to other commonly used breakfast fruits, but grows on a curious type of palm-like tree. Another food which can sometimes be used with success in elimination diets is pineapple juice.

Source of protein. Persons who are sensitive to beef and mutton might perhaps be able to eat reindeer meat, and it is conceivable that some day they will be eating the canned or frozen meat of sea mammals such as whales, porpoises and seals. Unfortunately, persons who are sensitive to fish seem often to be sensitive to every variety they have ever tried.

Those who cannot touch cow's milk can secure goat's milk in cans, and artificial milks are being made from such foods as soy beans and almonds. Already there are several substitutes for butter on the market, but fortunately, only the most extremely milk-sensitive persons need to use them.

Importing houses. Fortunately in large cities where there is a large immigrant population there are stores where one can buy almost every type of food known to man. From now on, these stores are likely to be patronized not only by women with shawls over their heads, but also by sufferers with allergic diseases.

SUMMARY

In the beginning, allergists had to be mainly concerned with the taking away of foods. Now more attention must be paid to the replacing of the hurtful foods with harmless ones. The problem of doing this is often difficult. Some highly food-sensitive persons could be saved from much distress if all the constituents of processed foods were listed on the label.

Approximately 60 per cent of Americans are somewhat food-sensitive, and perhaps 2 per cent are highly food-sensitive.

There is need in all large cities for bakeries that will supply breadstuffs made without wheat, egg or milk.

It is probable that many highly food-sensitive persons could widen their diets by searching the world's markets for new foods. Suggestions have been made as to some of the foods that might be tried. Research needs to be done also to see if some foods could be detoxified or in some way rendered harmless to sensitive persons.

Peritonitis Due to Ruptured Acute Appendicitis in Children; Influence of Delay on the Operative Mortality*

By

ROBERT ELMAN, M.D.

ST. LOUIS, MISSOURI

EARLY diagnosis and efficient treatment will undoubtedly lower the mortality in acute appendicitis; about this there is general agreement. Education against the pernicious prevalence of purgatives is another factor which must be emphasized. If the excessive number of ruptured appendices coming under our care were reduced or eliminated, there would probably be a scant 1,000 rather than the toll of 20,000 deaths each year from acute appendicitis. Until this time occurs, every surgeon is confronted with patients whose appendix has already ruptured and who present manifestations of peritonitis, local or general; it is almost entirely in this group that the fatal cases occur, and the problem of reducing the mortality is an urgent one. This is especially true of children; the present report is concerned only with patients under 14 years of age.

There are in general two points of view in regard to the operative therapy in patients with peritonitis from ruptured acute appendicitis. One group of surgeons urges immediate operation in order to reach the lesion as soon as possible and to remove the source of the infection by appendectomy. The second group takes the stand that postponement of operation allows the infection to become more localized, increases the resistance of the patient, and results in a lower mortality. The study upon which the present paper is based comprises patients treated according to both points of view. An analysis of the results has proved illuminating because of the definite differences in the findings in each group.

PREVIOUS OBSERVATIONS

In spite of the tremendous literature on the treatment of acute appendicitis, it is difficult to gather direct data, in children at least, on the relation between mortality and the period elapsing between admission and operation. With many instances the reports comprise both adults and children; because the situation in children is always more serious and the progress more rapid, the question of deferred operation may perhaps be answered differently depending on the age of the patient. In those surgeons advising the deferred operation, moreover, no mention is often made as to the extent of delay, although where the Ochsner treatment is designated, presumably a lapse of several days at least is indicated. An excellent statement of the confused status of the literature will be found in a paper by McKenty (1).

As an advocate of the deferred operation in spreading peritonitis, Coller and Potter (2) find their mortality greatly reduced since this policy was adopted,

from a very high figure to 9.3%. Of those under 16 years of age, the mortality was slightly higher, 12.5%. Horsley (3), on the other hand, advises immediate operation, reporting a low mortality of 3.1% in patients with peritonitis; no figures are given in regard to the deferred operation, since this procedure was not carried out.

Turning to the opposite side again, Guerry (4) reports a mortality of 8.2% in patients with diffuse peritonitis operated upon at once; with the deferred operation (Ochsner therapy), the mortality was 1.6%. He is therefore an enthusiastic advocate of the latter policy. Stanton (5) reports similar findings; neither of these authors have classified their patients according to age. Pattison (6), though reporting no data on the question of deferred operation, advises immediate operation in every case of advanced peritonitis as long as the patient is in good condition; conservative therapy is relegated to those who are in any degree of shock on admission. A similar point of view is expressed by Maes and McPetridge (7) who adopt the expectant treatment in adults with many misgivings, but do not even consider it in children; they report no data on this point. Keyes (8) and Stone (9), who made extensive studies of acute appendicitis in children did not go into the question of the immediate vs. delayed operation. In the British literature there is a similar, though perhaps more sharp difference of opinion. In general, therefore, it is difficult to draw accurate inferences from most of the cases reported. For this reason no résumé is attempted; the data herein is therefore presented without further reference to those of others.

COMMENT ON PRESENT FINDINGS

The clinical data for this study were obtained from consecutive admissions to the St. Louis Children's Hospital up to January 1, 1936; all cases were selected with a final diagnosis of acute appendicitis with rupture resulting in a local or general peritonitis. All of the patients were operated upon, and the anatomical diagnosis was based on the findings at laparotomy. On this basis the collection of the cases was nearly always easy; in only a few cases was an actual peritonitis present with an unruptured appendix; these were excluded. On the other hand, a few patients had a definite local or general peritonitis, although the appendix was not found; these cases were included if the origin of the infection seemed definitely appendiceal. No attempt was made to divide the cases into those with local and those with general peritonitis; this was often difficult clinically and sometimes impossible, even at laparotomy. It was a frequent experience to find the lesion at operation quite different from the one expected clinically. For example, a mass, supposedly an abscess, would prove to be indurated

*From the Department of Surgery, Washington University School of Medicine and the St. Louis Children's Hospital, St. Louis, Missouri. Presented at a meeting of the St. Louis Surgical Society, November 17, 1937. Submitted July 31, 1938.

omentum surrounding an appendix which was not even ruptured. Again, the abdominal signs would suggest a diffuse peritonitis, whereas at operation clear fluid would be encountered in the general peritoneal cavity with pus localized about the appendix. On the other hand, a mass which was actually due to an abscess was often found to be associated with a general peri-

course of the infection. However, it is difficult clinically to tell just when the appendix has ruptured; this is in contrast to the exact determination of when the appendicitis started. These considerations are important, because they have a bearing on the decision of the surgeon as to the proper time for operation once a peritonitis is present, or presumed to be present.

CHART 1

Mortality of all "ruptured" cases arranged according to the time of operation

	Hours elapsing between admission and operation							Total
	1	2-1	5-7	9-11	12-18	18-24	Over 24	
Cases	17	114	7	5	8	13	17	181
Deaths	4	14	2	2	1	1	4	28
Mortality	26%	12%	30%	40%	12%	8%	23%	15.5%
138 cases mortality 14.5%				43 cases mortality 18.5%				

tonitis because pus had burrowed through and broken into the general peritoneal cavity. This discrepancy between the bedside impression and the operative findings is especially true in children, as most observers agree. For these reasons it was felt that no practical advantage would be gained by such a classification, at least as far as the present discussion is concerned.

In all, 181 patients were studied; these were first arranged according to the time elapsing between admission and operation, and further subdivided into two groups, the "toxic" and "non-toxic." The separation into two groups in these children was not particularly difficult and was based to a large extent on the observations of the pediatric staff. No arbitrary elevation in the temperature or pulse rate was taken, although the children who were obviously very ill always presented a high fever and fast pulse. In most cases, however, the general appearance and behavior of the child was more indicative of toxicity; the existence of severe prostration was always assumed to be of great significance. There were 33 patients in the "toxic" group; the remainder were classified as "non-toxic." It might be assumed that the difference in the toxic manifestations were always due to a difference in the duration of the disease. This was not necessarily true, however. Many of the very toxic patients had taken ill but 21 to 48 hours before admission, whereas a number of those in the "non-toxic" group presented a history of several days since the onset of the attack. It must be assumed that the virulence of the organism or organisms played an important role in the severity of the general reaction. This conception fits in, of course, with experience in other types of serious infections which threaten life. It has become the custom to correlate mortality in acute appendicitis with the duration of the disease. This is true, if one considers *all* cases of acute appendicitis, both ruptured and unruptured; obviously, any delay immediately following the onset allows rupture to occur and will increase the mortality tremendously. Once rupture occurs, the duration of the disease still plays an important role in the mortality, but the virulence of the organism invading the peritoneal cavity probably plays an equal, if not a greater part in the

The accompanying charts reveal the main findings and really require little additional explanation. It will be noted that the mortality of the whole group was 15.5%; in the "non-toxic" group, however, only 6% died, whereas of those entering the hospital with "toxic" manifestations, 57% succumbed. In Chart 1 all cases are arranged according to the hour of operation; the mortality shows no consistent trend in the various groups operated upon at various intervals following admission. In the great majority of these patients, to be sure, operation was carried out within a few hours; this, indeed, was the usual policy. In the others, the delay was often a matter of extraneous circumstances. In a few cases it was due to difficulty in getting permission from parents or guardians; in many, however, the question of diagnosis was responsible. In general, they form such small groups that little significance need be attached to their differences in respective mortality. It should be noted, however, that, taking all cases, there seems to be no progressive lowering of the mortality with increasing delay; indeed, a mortality of 14.5% was present in those operated on within 8 hours following admission, whereas of those operated on after 8 hours 18.5% died. This difference is too small, however, to assume much significance from statistical point of view.

Much more decisive findings are observed if one separates the cases into the "toxic" and "non-toxic" groups. Thus, in the "toxic" group, the period of time elapsing between admission and operation seems of definite significance. (See Chart 2). A mortality of 70% in those operated on at once in contrast to a figure of 30% in those operated on 9 to 21 hours later indicates the value of delay in this type of patient. The reason for this difference is easy to understand and becomes obvious when one considers the fundamental considerations in regard to the operability of very sick children. Most of the children in this "toxic" group were extremely dehydrated from incessant vomiting; many had been ill-treated in the home; they had been given repeated cathartics and other medication, had had no rest, and in many cases had traveled a long distance, often without provision for recumbency. It is not surprising that such a child, if taken

to the operating room and given a general anesthetic, will almost surely die. On the other hand, if the child is put to bed, given good nursing care, dehydration corrected by parenteral fluids, rest achieved by physical or pharmacological means, dilatation of the stomach relieved by gastric lavage, transfused if

CHART 2

Mortality of "toxic" cases arranged according to the time of operation

	Cases	Deaths	Rate
Operation 1 to 8 hours* after admission	23	16	70%
Operation 9 to 48 hours** after admission	10	3	30%
Total	33	19	57%

*Most of these patients were operated on within 3 hours after admission.

**Only one patient was operated on 48 hours after admission, because he also had measles, which was largely responsible for the fatal outcome 2 days later.

necessary, fecal impaction eliminated—if all these procedures are carried out, and the operation then performed, after the general condition has improved sufficiently to permit it, the mortality will be cut to less than half.

In the "non-toxic" group (see Chart 3) the findings are the reverse of those in the "toxic" group, i.e., the mortality was lowest (3.5%) in those operated upon within 8 hours after admission, whereas it was four times greater (15%) in those operated upon 8 hours or longer after admission. Thus, in patients entering the hospital in good condition, delay increases the likelihood of a fatal outcome considerably. This is not surprising, for it bears out a fundamental principle,

CHART 3

Mortality of "non-toxic" cases, arranged according to time of operation

	Cases	Deaths	Rate
Operation 1 to 8 hours after admission	115	4	3.5%
Operation 8 hours or longer after admission	33	5	15%
Total	148	9	6%

i.e., that where the source of a peritonitis can be eliminated safely, the earlier it is done the more likely is the infection overcome.

The type of anesthetic and the operative procedure itself undoubtedly play important parts also; these factors are not considered in this report. In general, the cases herein described were all operated upon by the same group of surgeons, using a similar technic and the same anesthesia and anesthetists. Differences in mortality are referable therefore to the other factors mentioned, notably the period of time elapsing between admission and operation.

Comparison of the findings in Charts 2 and 3 leads to certain clear-cut inferences. If a child enters the hospital prostrated, dehydrated, toxic, obviously unfit for an operative procedure, delay is indicated, regard-

less of the period of time the child has been sick. How long the delay should be cannot be answered from the present findings, because, with one exception, operation was not deferred beyond 24 hours. Although the mortality was less than half in those operated on after a delay of more than 8 hours, it might be argued that the mortality might have been still lower if 36 or 48 hours or more had elapsed before laparotomy. This point cannot be answered on the basis of the present findings. Certainly, however, the advantage of delay in order to make the patient more able to withstand operation is clearly shown and should be emphasized. If a child is not toxic, however, the necessity of immediate operation is indicated by the increased mortality in those operated on after a delay of 8 hours or more. These differences in mortality may be graphically expressed as follows:

Toxic cases: mortality of operation within 8 hours of admission 70%
 Toxic cases: mortality of operation after 8 hours 30%
 Non-toxic cases: mortality of operation within 8 hours of admission 3.5%
 Non-toxic cases: mortality of operation after 8 hours 15%

The danger of a policy of unqualified delay is obvious from these findings. Unfortunately, the idea that delayed operation is advantageous in peritonitis from acute appendicitis with rupture has been accepted by a good many physicians without regard to the potential harm of such an inference. This is particularly true when applied to the care of such patients in the home. The necessity of early diagnosis and treatment of acute appendicitis in a hospital cannot be too strongly emphasized. If delay is advisable, the decision should rest with a competent surgeon; under such circumstances the patient is enabled to receive the necessary care which delay justifies. Indiscriminate advocacy of delay may be partly responsible for the unfortunate increasing mortality in acute appendicitis. The general practitioner has heard his surgical colleagues speak of the advantages of the so-called Ochsner therapy, and as a result he is tempted to follow this advice whenever he is confronted with a case of acute appendicitis. He does not realize that this type of expectant or non-operative therapy is reserved for a really small percentage of patients with peritonitis; indeed, patients who should not have been permitted to develop peritonitis. Moreover, it is occasionally difficult to tell clinically, even by an experienced surgeon, whether there is a peritonitis and whether it is spreading or not. From the findings herein presented, the necessity of immediate operation is clear whether the appendix is ruptured or not, whether a peritonitis is present or not, provided the child is in a good condition to withstand the procedure. If the child is not in such a state, delay is advisable; such delay is valuable because it enables the surgeon to carry out non-operative therapeutic procedures which improve the general condition sufficiently to permit operation for elimination of the source of the infection and in certain cases to allow localization of the infection to take place. Thus the question of immediate or deferred operation is answered not so much by an estimate of the extent of the lesion, but upon the extent to which the lesion has affected the general condition, i.e., the operability.

CONCLUSIONS

The evidence herein presented indicates that children with acute ruptured appendicitis entering the hospital in good general condition should be operated upon at once. Thus the treatment is the same as that of unruptured acute appendicitis. In contrast, those entering the hospital severely ill should not be operated upon at once, but only after a delay, which is utilized in improving the general condition of the patient by correcting dehydration, relieving distension, achieving rest, giving transfusions, etc., and in some cases long enough to allow localization to occur. The decision as to delay should not be made in the home, but while the child is in the hospital under the care of a competent surgeon. On the basis of the present findings it would seem that the problem of the deferred operation depends not so much upon the presence or absence or degree of peritonitis, which may be difficult to estimate accurately at the bedside, but upon the general condition of the child, i.e., the operability. In any case, the necessity of hospitalizing

every child with acute appendicitis is clearly indicated; immediate or delayed operation can best be determined "on the threshold of the operating room."

SUMMARY

1. In 181 children operated on for peritonitis following rupture of acute appendicitis, operation was fatal in 28, making the mortality 15.5% of the 181 children, 33 entered the hospital extremely ill ("toxic"); 19 of these patients died, making the mortality 57%. In the remaining 148 ("non-toxic") patients, 9 succumbed, making the mortality 6%.

2. In the 181 patients as a whole, no definite correlation could be found between mortality and time elapsed between admission and operation.

3. In the "toxic" group, the mortality was 70% in those operated upon at once, and 30% in those operated upon after a delay of 9 to 24 hours.

4. In the "non-toxic" group, the mortality was 3.5% in those operated upon at once, 15% in those operated upon after a delay of 9 hours or more.

A Report of Ten Cases of Pellagra Treated with Nicotinic Acid

By

VERN H. MUSICK, M.D.
OKLAHOMA CITY, OKLAHOMA

FUNK in 1911, 12, 13, stated that his II factor C₁₂H₁₀O₂N was nicotinic acid which was isolated from rice polishings and yeast. It had by itself no therapeutic action in treating polyneuritic pigeons but did augment the actions of the other fractions. His I fraction from yeast caused improvement in polyneuritic birds, while the I and II fractions cured them readily, thus, showing that nicotinic acid or II greatly augmented the action of I. When all three fractions were added even greater improvement was noted. This work was later confirmed by Szymanska and Funk and Casimar Funk.

In 1918, Golberger, Wheeler and Sydenstricker (1), after considerable experimentation, declared that pellagra as the disease is known, was a fusion of two closely related syndromes with possibly two separate factors as the cause. Elvehjem, Madden, Strong and Wooley (2) in September, 1937, reported that nicotinic acid would cure black tongue in dogs. Street and Cowgill (3) confirmed these findings while Chick, Macrae and Martin (4) cured black tongue in swine. Sebrell, Onstott, Fraser and Daft (5) found that 6 mg. of nicotinic acid twice a week would prevent the disease in dogs on a pellagra producing diet. Spies, Cooper and Blankenhorn (6) treated four cases of human pellagra while Fouts, Holmer, Lepovsky and Jukes (7) reported that 500 mg. of nicotinic acid was not as

good as liver filtrate. Harris (8) reported improvement in five cases treated with nicotinic acid. Spies again recommended that the patient be given a well balanced diet with nicotinic acid. Smith, Ruffin and Smith (9), added a case, and suggested nicotinic acid in drinking water as a pellagra preventing caution. Sebrell and Onstott (10) found that dogs, on a black tongue producing diet while taking nicotinic acid will die if riboflavin is absent.

METHOD OF STUDY

The ten pellagrans selected for this study had a symmetrical dermatitis characteristic of the Golberger type, with the exception of Case 7, who gave a history of dermatitis, but at the time of the study, was entirely free. Patients having a secondary type of pellagra due to organic disease, were carefully excluded, and none gave a history of chronic alcoholic addiction. There was included one case (Case 1), whose chief complaint was a thick leathery dermatitis on the backs of both hands with moderate abrasions. There were three cases presenting a dermatitis on the back of the hands, with thick indurated skin without abrasions (Cases 2, 9 and 10). Five cases had the acute red dermatitis with thin skin (Cases 3, 4, 5, 6 and 8). The one case of chronic glossitis and stomatitis gave a typical pellagrous history (Case 7).

All of the patients except one (Case 5) were treated ambulatory; however, this case, because of the severe glossitis and stomatitis, was unable to swallow food, and was, therefore, on a deficient diet. No changes were made

Fig. 1. The "Pellagrous Boot" of Case 6 before treatment was instituted.

in any of the patient's diets and the environment was unchanged. Their diet deficiencies were confirmed during the course of treatment. Organic disease was ruled out by thorough physical examination, laboratory tests and X-ray examinations. No other medication except nicotinic acid was given during the course of observation.

RESULTS

Observations on the chief objective and subjective symptoms are summarized as follows: It was noted that patients with thin skin, who had the typical pellagrous dermatitis, responded to treatment with nicotinic acid within ten days (Cases 3, 4, 5, 6 and 8). Subjects (2, 9 and 10), with the thick dermatitis, showed improvement and cure in two months. Subject (1) took 76 days to completely clear the abrasions.

The stomatitis and glossitis gave the quicker response to treatment with nicotinic acid, the mouth being clear two or three days before the dermatitis subsided (Case 3, 4, 5 and 9). The stomatitis of (Case 7) had been present for two years and responded much more slowly than the more acute types. The tongue in this case was atrophic, thickened, beefy red, and stiffened. Satisfactory response in 36 days required rather large doses of nicotinic acid.

The diarrhea was controlled in (Case 2) in three days with 50 mg. of nicotinic acid a day; however, it recurred again on the 14, 15 and 16th days when 100 mg. of nicotinic acid was being given. When this patient ran out of medicine on the 50th day, the diarrhea recurred on the 52nd day and continued until administration of 200 mg. per day. It again recurred on the 66th day after 200 mg. of nicotinic acid per day had been given for six days. The diarrhea of (Case 8) was controlled with 50 to 100 mg. of nicotinic acid a day, but recurred on the 32nd, 33rd, 34th, 35th and 36th days while 150 mg. was being taken. The diarrhea of (Case 8) was controlled readily with 50 mg. of nicotinic acid but recurred on the 30th day under administration of 150 mg. and again on the 42nd day under administration of 300 mg. The diarrhea of (Case 10) responded slowly to 100 mg. of nicotinic acid, taking ten days. It recurred again on the 22nd, 23rd, 24th, 25th and 26th days while 150 mg. was being administered a day. It also broke through on the 40th, 41st, 42nd, 43rd, 45th and 46th days on 150 mg. per day. Since this work has been completed, we have observed a patient whose diarrhea recurred on 600 mg. per day.

Fig. 2. The dermatitis of Case 6 on the tenth day of nicotinic acid therapy.

It was noted that the neuritis of (Cases 1, 2, 5, 7 and 10) was slightly improved while (Cases 3 and 9) became progressively worse. Although (Case 3) had no neuritis at the beginning of treatment, she developed, on the 36th day while 150 mg. were being administered a day, a rather severe generalized neuritis.

The general health was slightly improved in (Cases 1, 2, 3, 5, 7, 8 and 10) while (Cases 4, 6 and 9) showed no improvement or became slightly worse. (Case No. 9's) general condition became critical when he developed attacks of angina pectoris.

None of the cases had severe mental disturbances except (Cases 5 and 10). (Case 5) was acutely delirious. This quickly cleared following 100 mg. for three days. However, her memory and neurosis remained unchanged. (Case 10) had had severe mental symptoms with institutional care ten years previous. He now elicited a rather severe neurosis bordering on psychosis. He was benefited approximately 25% in two months.

REACTIONS FROM NICOTINIC ACID

Approximately 2,500-50 mg. nicotinic acid tablets and 300-100 mg. tablets were given to 31 pellagrins over a period of two and one-half months. No severe reactions occurred. The flush, tingling, and a sensation of heat to the skin of the face and arms was noted in most of the patients. 600 mg. of nicotinic acid a day have been given with no untoward reactions. All of the drug was administered by mouth. Burning of the stomach was quickly relieved by drinking water in sufficient amounts with the medicine.

CONCLUSIONS

First: Nicotinic acid, 50 mg. to 500 mg. per day, is specific in curing the acute dermatitis and glossitis of the Golberger type of pellagra.

Second: Prolonged use of 150 mg. to 500 mg. of nicotinic acid a day will cure the chronic dermatitis with abrasion and chronic glossitis of typical pellagra.

Third: Nicotinic acid in doses up to 500 mg. will partially control the diarrhea of typical pellagra.

Fourth: Nicotinic acid from 50 mg. to 500 mg. a day is of very little aid in the treatment of the neuritis and mental symptoms associated with pellagra in humans except those with acute delirium.

Fifth: The general health of the pellagrous patient

is only slightly enhanced by treatment with nicotinic acid (50 mg. to 500 mg. per day).

Sixth: There is probably another factor or factors,

other than nicotinic acid, which is necessary to completely cure the human pellagrous patient.

Nicotinic Acid furnished by Abbott Laboratories.

Studies on Water and Soap Enemas*

By

R. D. TEMPLETON

and

E. L. BORKON†

CHICAGO, ILLINOIS

THE Egyptians are said by Pliny (1) to have discovered the effect of enemas or clysters from the act of a bird called the ibis. "He washes the inside of his body by introducing water with his beak into the channel by which our health demands that the residue of our food should leave." The idea was probably obtained from the bird's habit of collecting oil from the preen-gland, situated close to the rump, with its long curved bill which it frequently dipped into the water as it preened its feathers. Evacuation of a liquid feces was probably often associated with the act of preening. These two acts were then correlated by the Egyptians and since they knew nothing of the preen gland nor of the common passage of urine and feces through the cloaca an erroneous conclusion was reached.

After the Renaissance, enemas became extremely popular as a general health measure but with the closing of the eighteenth century they became less a fad with the laity and more of a therapeutic agent among physicians. The chief interest became centered about the quantity, constituents and methods of administering enemas (2).

At the present time, enemas have a definite place in clinical medicine and yet much work needs to be done to determine the mechanism of action by which the various types elicit their results. Since colon activity, especially peristalsis, is usually considered an important mechanism in defecation our study has been limited to the circular muscle activity. In order to obtain records simultaneously from several parts of the colon a tandem balloon system (3) was used as modified by Templeton and Lawson (4) for the purpose of correlating proximal and distal colon activity.

A tandem system consists essentially of three bal-

loons arranged in linear order and connected by rubber tubes to respective manometers. The tubes fitted with coil springs to give the desired rigidity are fastened together with rubber cement. To make the compartments leak-proof, a base of rubber cement is molded about the tubes where the balloons are to be tied. Special balloons* 5 cm. long and 5 cm. in diameter at the center and tapering to 2 cm. in diameter at the two open ends are used. When completed the entire set is 20 cm. long with three compartments of 3 cm., each separated from one another by 5 cm. and a terminal 1 cm. which serves as a guide for insertion.

The manometer floats are simply inverted Wassermann tubes (5) with capillary glass uprights attached to their closed ends. Such floats can be sunk to the desired level simply by the quantity of manometer fluid held in the tube. The manometer caps (2 cm. tall) are held snugly against the manometers by means of a thin copper sheet inner lining. Celluloid elbows are used to connect glass writing points to the uprights. The points are held against a smoked drum at the desired tension by means of a glass upright attached to each brass cap by a flexible spring (6). Two tandem systems of three balloons each were used in this study enabling us to record simultaneously, activity from six segments of the gut. A special clamp (6) was designed to hold the desired number of manometers in such relation to each other that all could record in a vertical line.

For this study only trained cecostomized dogs were used. The dogs were taught to lie quietly with only a blind over their eyes for the length of time required for the experiment (up to 20 hours). One set of balloons, called the proximal set, was inserted through the cecostomy, and the second set by way of the anus.

Fig. 1. Part A. Two hundred minutes of a six balloon tracing. X to Y, control period of 100 minutes. 1, injection of 50 cc. of soap solution per rectum. 2, repetition of 1. Y to Z, 100 minutes of tracing following retention enema.

Part B. Diagrammatic graph of entire six balloon tracing of which an excerpt of the original is given in part A. X to Y corresponds to X to Y in part A. 1 and 2 represent 1 and 2 in part A. Y to Z corresponds to Y to Z in part A.

When in position, the balloon systems were tied in place by a rope harness about the dog's body.

The quantity of activity within any given time may be measured by the amplitude of activity or by the time spent in activity. The work reported in this paper considers only the latter. Since the colon is essentially periodic (7), it is possible to reproduce the spatial relationship of the active and quiet periods (Fig. 1) on graph paper. To accomplish this, two arbitrary rules were adhered to: First, the gut was considered active if the contraction or contractions lasted one minute or more. Second, the gut was considered quiet if two minutes or more intervened between contractions. By rigidly adhering to these rules the active and quiet periods of the colon were represented in sharp contrast.

In a study of the quantity of colon activity the technical difficulties met with in establishing identical conditions from day to day, make certain variations from a planned routine a likely occurrence. It is necessary, therefore, to know the extent to which colon activity may be influenced by such factors as insertion of the balloons, slight variations in balloon distention, training of the animal, noises, time of feeding, posture of the animal, temperature of the room, sleep, and disturbing stimuli.

Welch and Plant (8) observed a greater tone and activity in the proximal colon of unanesthetized dogs during the first portion of the tracings. Lawson and Templeton (9) observed irregularities in the first portion of the tracing similar to those of Welch and Plant. In general, our observations agree with the previous authors. Although the total activity of the entire colon in the first 50 minutes of an experiment is more irregular than that in the succeeding period, the difference is not sufficiently marked to require

discarding the first portion of the tracing, when a large number of experiments are performed. This irregularity in the first portion of the experiments is usually attributed to the effect of balloon insertions.

In order to obtain comparable distentions of each balloon and to repeat the same distentions from day to day regardless of the balloon system or animal used, a definite routine was strictly followed. First, only intestinal balloons of constant size (previously described) were used. Second, after the balloons had been inserted and secured in place, they were inflated and deflated several times with the manometers clamped out of the circuit, to smooth out their contour in situ. Third, with the water manometer returned to the circuit, six centimeters of water pressure were drawn against each balloon to insure comparable deflation. Fourth, eight centimeters of water pressure were built up in each manometer and after clamping off the free end of the T tube the positive pressure was then allowed to enter the balloon. Even though the above technique is rigidly adhered to, some uncontrollable deviation in the balloon inflations undoubtedly occur. However, deviations to the extent of 10 cm. of additional water pressure have previously been shown to have only a minor local effect (9). Judging from the character of the tracings obtained from day to day on the same animal or on different animals, any minor variations in balloon distention which we may have encountered, are negligible.

In all of our experiments, at least three weeks were permitted for recovery and training after the cecostomy. At the conclusion of the three week training period, tracings from the colon were obtained periodically. The quantity of activity recorded in the first tracings was not found to consistently differ appreciably from the quantity observed in the same animals two years later.

While training the animals, no precautions were

taken to exclude the ordinary noise met with under laboratory conditions—such as, conversation, movement about the room and so forth. In fact, during the training period, these noises were purposely exaggerated. Following such training, it was not possible to differentiate by a careful study of the record, when people were entering or leaving or when other ordinary noises occurred in the laboratory.

The influence of feeding the animal or filling the stomach has been studied by various investigators (8, 10, 11). Our observations were made 12 to 24 hours after the ingestion of food. The food consisted of about 5 pounds of a mixture of ground beef lung and white bread in proportions of 4 to 1 by weight, to which 50 grams of bone were added. No significant difference was observed in the quantity of colon activity recorded within the confines of this period.

In the majority of our experiments, the animals were kept lying comfortably on their side throughout the course of the observations. Some experiments, however, were obtained with the animals standing in Pavlov stalls. A comparison revealed no consistent difference in the duration of active periods in these positions, although the amplitude of the contractions was markedly affected.

The temperature of the room in which the experiments were conducted was maintained for the comfort of the animal during the Fall and Winter months; but there existed no adequate means of controlling the temperature during the summer months. Because of this variation it was possible to compare the motility recorded when the animals were panting and when they were more comfortable. Typical tracings under these conditions revealed a difference in character and height of motility, but no appreciable difference in the quantity was consistently related to the different room temperatures.

On many occasions during the course of experiments, animals were observed sleeping as indicated by the type of respiration, snoring, and rapid movements of the paws which occasionally even involved the legs and head, requiring that the animal be awakened to quiet him. During these periods no

change in the quality or quantity of colon activity was observed when compared with the preceding and following activity.

Lawson and Templeton reported that tetanizing currents applied to the distal colon with a strength sufficient to cause signs of discomfort, gave essentially negative results on motility except when the region near the internal anal sphincter was stimulated (9). In our observations, vigorous stimuli applied to the animal's body for admonition were followed first, by contraction of the abdominal muscles, (recorded in the tracing as a sudden rise and fall of the water level in the manometers) and frequently immediately afterwards by simultaneous contractions of all recording segments. In some cases, no other change in the activity was observed; while in others, these simultaneous contractions were followed by a temporary inhibition of activity.

	100 cc. Soap Solution	18	14	4
	200 cc. Soap Solution	18	13	5
Continuous Controls		24	9	15
Interrupted Controls		18	8	10

Having carefully studied those variations in the experimental procedure which might be encountered in the course of an experiment, the technique employed seemed sufficiently standardized to study the effects of intracolonic injections on large bowel activity. There is, indeed, considerable variation in the quantity of colon activity as recorded by our method from day to day in the same animal. This difference, however, is not explainable on the basis of small variabilities in any of the controllable factors we have studied, thus necessitating several control tracings for each experiment. Especially large differences in the quantity of activity may be seen when the charts of different animals are compared. In one animal the colon may be consistently active less than 50% of the time, while in another activity may be consistently present 75% of the time or more. Naturally such a variability necessitates the use of the same animals throughout the course of any experiment—controls can not be obtained on one animal and the experimental procedure followed on another.

Our selection of substances for intracolonic injections was narrowed to the most commonly used clinical enemas, namely, oil, tap water and soap solutions. In preliminary observations on the relative

efficiency of oil and a one and one-fourth per cent soap solution for eliciting defecation, we found the latter to be much more effective (12), while the efficiency of tap water was found to be comparable to that of the soap solution.

A study of the effect of intracolonic injections on colon motility may be considered from two points of

Only those interrupted experiments were considered in which the animals defecated when given their freedom.

One hundred and fifty-one observations were made on the influence of enemas on the same animals that were used in the control study. Of these, 81 were continuous experiments in which 100 cc. or 200 cc. of

view: 1. the effect associated with the retention of enemas and 2. the residual effect observed after the expulsion of the enemas. The first study, previously reported (13), was concerned with observations on 100 and 200 cc. quantities of white mineral oil. In the continuous experiment, the oil was retained while in the interrupted experiment the animals were permitted to expel the enemas. Under both conditions, but especially in the continuous type, the quantity of activity was observed to be greater following the injection of oil, than in the control experiments.

To control the work on soap solution and tap water enemas, 45 experiments, each of 400 minutes duration, were performed on 4 dogs in which no enemas were given. Of these 27 were continuous experiments in which the animals were kept on the table the entire 400 minutes without removing the balloons. Eighteen were interrupted experiments in which, at the conclusion of 200 minutes, the balloon systems were removed, the dogs allowed their freedom outdoors, and after a 30-minute interval the experiments resumed.

tap water or 1¼ per cent soap solution were injected at the end of a 200 minute control period. The enemas were injected by way of a tube previously fastened on the distal set between the middle and terminal balloons. The animals were not permitted to expel the injected material until the remaining 200 minutes of the experiment were completed. Seventy interrupted enema experiments were conducted in which, at the conclusion of 200 minutes, 100 or 200-cc. of tap water or 1¼ per cent soap solution were injected by way of the previously mentioned enema tube. The balloon systems were then removed, the animals allowed their freedom out doors as in the controls, and after a 30 minute interval, the experiments resumed on those animals which expelled the enema.

It has been common practice to compare the motility immediately preceding an experimental procedure with that which follows shortly afterwards to relate cause and effect. We have therefore, tabulated (Table I) our results to show the number of tracings in which the introduction of enemas was followed by an in-

crease in colon activity for comparison with the number in which a decrease in activity followed the enema administration. In this tabulation, only the 50 minute periods immediately preceding and following the injection of the enema were considered.

In the group of continuous experiments, the introduction of 100 cc. of water on 24 occasions was followed in only 7 by an increase in activity. The administration of 200 cc. of water in 20 experiments was followed in 11 by an increase in activity. The introduction of 100 and 200 cc. of soap solution into the colon in 18 and 19 experiments respectively were followed 11 times each by an increase in activity. These figures indicate that only when 100 cc. water enemas were used was there a decrease in the colon activity in the majority of the continuous tracings. A decrease in activity, however, was observed in more than two-thirds of the interrupted experiments whether water or soap solution in 100 or 200 cc. quantities were used. This method fails to consider the degree of increase or decrease in activity and does not take into consideration the expectancy curve which is obtained from control experiments in which no enemas were introduced. A study of comparable time periods in control tracings revealed an expectancy increase in activity in 15 of 24 continuous experiments, and in 10 of 18 interrupted experiments.

The average percentage of activity in the experimental groups compared to the control group is probably more significant than the fact that some degree of increase or decrease in activity followed the administration of an enema in a certain number of experiments.

In the continuous experiments (Fig. 2) during the first 50 minutes following the enema injection, the average activity was below that of the controls for the same period. During the next 50 minutes the per cent of activity in all experimental groups rose toward or actually above that of the control group. In the last 100 minutes, the quantity of activity in the experimental groups was well above that of the controls.

In the interrupted experiments (Fig. 3) where either tap water or soap solution was used the effect was practically the same, whether in 100 or 200 cc. quantities. During the first 50 minutes following the administration, activity was below that of the controls. In the next 50 minutes, the percentage of activity in all groups returned to approximately that of the controls and became for the succeeding 50 minutes slightly above the control level. During the last 50 minutes, the per cent of activity in the experimental groups again dropped below that of the control level. Our observations are not in accord with those of Yamamoto (14), who reported, from roentgen ray studies, an acceleration of the movements of the colon following soap water enemas. We are not able to interpret the efficiency of soap solutions in eliciting defecation as Hurst does (15), on the basis of increased peristalsis.

In all experimental results whether the procedure involved continuous or interrupted experiments, soap or water enemas, in either 100 or 200 cc. quantities, the percentage of activity of the first 50 minutes was less than that observed in the respective control experiments. In direct contrast to this, we reported that oil enemas whether in 100 or 200 cc. quantities, in continuous or interrupted experiments caused an in-

crease in activity above the controls which reached a peak in the first 50 minutes (Table II).

If high activity is an index of a defecation urge, the augmentation following oil, reported by us, should be associated with a higher percentage of defecation than soap or water. Since the reverse is true, namely, soap solution and tap water are more efficient in eliciting defecation, it is apparent that, under these conditions, the defecation urge is associated with the less active colon.

In the light of these results and those previously reported (16), we may consider enemas as having at least two actions. First, an effect on colon activity, and second, an initiation of the defecation urge. These two actions may conflict under experimental conditions. If the stimulus to defecation is excessively strong due to the character of the enema and the animal is under conditions not customarily associated with defecation, the act may be inhibited. Such inhibitions may serve also to decrease the activity. On such grounds the *modus operandi* in the depression of activity obtained with soap and water enemas during the first succeeding 50 minutes following injections may be explained. On the other hand, the stimulus to colon motility may be moderately strong and yet elicit only a mild defecation urge. Under such conditions, the colon activity may rise above the control level, as reported by us with oil enemas, without initiating an inhibitory mechanism to that motility.

It is possible that the inhibition of circular activity is more frequently associated with the urge and the act of defecation than is an augmentation of such activity. Relaxation of the gut may elicit a defecation impulse by a mechanism similar to that by which distension acts. Defecation may then be a voluntary act in which the contents of the distal colon are forced through the relaxed tube.

SUMMARY

1. The balloon technique for the study of colon motility is discussed.
2. The influences of extraneous factors commonly encountered in an experiment are discussed.
3. Enemas of soap solution or tap water were found to be more efficient in producing defecation than white mineral oil.
4. For the purpose of quantitating colon motility, first, the active and quiet periods are shown in sharp contrast, and second, the time spent in activity is expressed on a percentage basis.
5. During the first 50 minutes following the administration of soap or water enemas, in the continuous experiments, the percentage of activity was found to be less than that of the controls.
6. In the interrupted experiments, when expulsion of the enema was permitted, a similar but more lasting decrease in colon activity was observed than in the continuous experiments.
7. The decrease in colon activity associated with soap or water enemas is in marked contrast to the results previously obtained with oil enemas.
8. Under the experimental conditions used in this study, soap solution and tap water enemas were found to exert comparable effects on colon activity.

This work was conducted under the general supervision of Dr. A. J. Carlson to whom we are greatly indebted.

Anorexia and Gastric Motility*

By
DOROTHY P. GULLIKSEN, ALMA FOGELBERG
and
LUDWIG KARDOS
CHICAGO, ILLINOIS

THE experimental work presented in this paper was undertaken for the purpose of determining the relation between gastric motility and anorexia in children. The frequency with which this type of disorder comes to the attention of physicians has been investigated by Bartlett (1928). Of the children attending an outpatient department, 24% were anorexic and a third of these showed no lesions which might account for the difficulty. They were classed as cases of functional anorexia when they showed definite signs of malnutrition as well as being reported poor eaters by the parents. Investigators (Moseley, 1925; Johnston, F. A., 1926; and Dumond, H. E., 1928) who visited homes in both city and country communities reported "non-hunger" in 2/3 of the city children, who were a group living in comfortable homes, and in only 1/3 of the country children. Only 5% of city children by Stolz (1934) gives information on both the frequency of occurrence of anorexia and also on its persistence in a group of children in their 2nd year of life. Information was obtained from the mothers' reports. At 21 months of age 11% of the group was anorexic and at 36 months, 26% of the group was anorexic. No child was reported as showing anorexia evidence on the persistence of good or poor appetite is given (Thurston, 1929) in a report on the time taken by nursery school children to eat a standardized meal. The author states that "a study of the individual children shows no consistently fast or slow eaters, and there are only 14 of the 41 children who tend to be consistently average." Davis, C. M. (1928) in a study of self-selected diets by infants of weaning age also mentions the variability of appetite. The above studies indicate that though a fairly large number of children in the groups studied showed anorexia, repeated observations showed persistent anorexia to be relatively uncommon.

CAUSATION

(1) One of the most frequent explanations of anorexia in children, when it is not associated with diseased conditions, is that the child has developed poor eating habits. (Abt, 1924) (Porter, 1925). Aldrich (1925), presents the view that anorexia frequently develops in children when

the parents attempt to force them to eat definite amounts and kinds of food, often in an attempt to make them attain a certain standard of height and weight. He presents evidence from a questionnaire study tending to show that anorexia does not develop where parents have been instructed not to force children to eat. Johnston (1926) discussing the studies previously mentioned on city and country children, attributes the higher figures for "non-hunger" found among city children as compared with rural children, to the greater prevalence of over-solicitude among city mothers.

(2) Other writers who agree with the first group that poor eating habits are responsible for anorexia, make the additional point that physical consequences of the low food intake often intensify and prolong the state of anorexia. Venables (1930) states that anorexia is due to psychological causes, but is perpetuated by such factors as constipation, feelings of discomfort, distention and nausea on taking food. He reports favorable results with forced feeding to restore the normal eating habit in adult cases. Langdon Brown and Crookshank (1931) report similar observations. Kugelmass and Samuel (1931) believe that anorexia is due to emotional disturbances or other psychological causes which in turn produce functional atony of the gastro-intestinal tract, constipation and other symptoms, including anorexia. No direct evidence on the motility of the gastro-intestinal tract is given either before or after their dietary treatment of anorexic children, so that it is not possible to verify the assumption that an atonic condition of the gastro-intestinal tract existed or that any change in the tonicity was brought about by the dietary treatment.

(3) A third group of writers may be placed together in assuming that some constitutional defect is primarily responsible for anorexia observed in children. A frequently mentioned factor of this type is a gastric atony which is thought to be one manifestation of a type also characterized by a generally poor muscular development, associated with a frail body build. Anorexia, poor nutrition, and a tendency toward digestive disturbances are thought to result from the gastric atony. Rupp and Schlutz (1930) studied the motility of the empty stomach in normal and in malnourished asthenic children. The authors conclude that the normal children's stomachs exhibit greater activity in terms of length of an activity period, than those of subjects with a frail asthenic build, and that among the latter group those with anorexia and other gastro-intestinal complaints showed the least gastric activity. The authors recognize that the conclusion

tentative since they are based on only two selected records from each child. Lucas and Pryor (1931) report an association between anorexia, constipation, poor nutrition and a slender type of body build, though the precise relationships are not stated. Gastric atony is assumed but no observations on the motility or tonicity of the gastro-intestinal tract are made.

There is on the other hand evidence which conflicts with the view that anorexia is characterized by decreased gastric motility. Taylor (1917) found the contractions of the empty stomach in infants who nursed feebly were of normal intensity. In other types of mild disturbance where the usual sensations of hunger and appetite are absent, there is no depression of gastric motility. Carlson (1916) states that accompanying moderate degrees of fever there are "objectively normal gastric contractions parallel with the epigastric feeling of 'sick stomach,' nausea, headache, depression, no thought of or desire for food." Smith (1927) states that in the early stages of Vitamin B deficiency where animals had shown anorexia for the Vitamin B deficient diet for four days, the hunger contractions were not distinguishable from those of normal dogs. It is significant that moderate disturbances accompanied by anorexia may exist without diminution of gastric activity. Presumably the anorexia described in children where there is no obviously diseased condition present, may also be classed as a moderate disturbance, since the children carry on ordinary activities.

EXPERIMENT

The present study was undertaken to obtain evidence on the relation between the so-called functional anorexia in children, and the activity of the empty stomach. Children in the Mooseheart community were first observed to find cases of obvious anorexia, such as might be noticed by a parent in an ordinary community, and might then be brought to the attention of a pediatrician. Observations on some 200 children between the ages of 9 and 15 years were made by workers from the Mooseheart laboratory. For a

period of two weeks a worker recorded the number of servings eaten at a meal by each of the six or seven children sitting at a table, and also noted the children who seemed to him to be very good or very poor eaters. In order to rule out temporary disturbances of appetite, the observations were repeated by another observer after a period of several months, the children being regrouped at the tables so that comparisons were not made between the same six or seven children as before. Each group was made up of children of about the same age. Where the record of food intake and the observer's opinion both indicated that the child was a poor eater, he was classed in the anorexic group. The anorexic group were slender and more or less underweight for their height and age. The children who were good eaters during the two observation periods were designated the non-anorexic group.

Using the method described by Carlson (1916), records of the motility of the empty stomach were made on 18 children, 6 from the anorexic group and 12 from those who had been found to have good or hearty appetites. On some of these children the test not only included a period of gastric activity, but also the following period of relative rest and the beginning of a second period of gastric activity. At least five tests were completed on each child without disturbance in the form of colds, restlessness, etc. In some cases as many as 22 tests were made on one child.

RESULTS

(1) Prevalence of anorexia. Of the 200 children observed 13 (6.5%) had poor appetites as judged by their food intake and two observers' opinions of their appetite. Those showing very poor appetites were found to be from 10% to 22% underweight for their height and age by the Baldwin Wood tables. Children

Summary of Measurements

Measure	Anorexic Subjects				Non-Anorexic Subjects				Diff.	S. D. of Diff.	P.	Evaluation
	No. Subjects	No. Tests	Av.	S. D. of Distribution	No. Subjects	No. Tests	Av.	S. D. of Distribution				
1. Duration of activity period.	6	76	62.2 Mins.	23.55	11	150	74.6 Mins.	27.1	7.41	4.0	0.1 to 0.05	No significant difference between anorexic and non-anorexic subjects.
2. Height of large contractions.	6	73	2.5 Cms.	1.26	12	153	2.8 Cms.	1.51	0.279	0.025	Less than 0.01	Significantly higher contractions in non-anorexic subjects.
3. Number of contractions.	6	75	66.5	39.65	12	153	48.5	29.35	18.0	5.1	Less than 0.01	Significantly more contractions in anorexic subjects.
4. Duration of interval between periods.	3	27	35.2 Mins.	18.3	9	63	61.6 Mins.	23.85	26.4	4.6	Less than 0.01	Significantly shorter interval in anorexic subjects.
5. Duration of individual contractions.	4	42	38 Secs.		9	160	43 Secs.					Shorter duration in anorexic subjects.
6. Duration of incomplete tetany.	6	50	7 Mins.		12	93	7 Mins.					No difference between anorexic and non-anorexic.
7. Number of contractions in incomplete tetany.	6	49	16		12	93	16					No difference between anorexic and non-anorexic.
8. Duration of individual contractions in incomplete tetany.	6	49	26 Secs.		12	93	24 Secs.					No difference between anorexic and non-anorexic.

were not included in the anorexic group when their lack of appetite was associated with recovery from a severe illness or similar physical disturbance. Medical records on the group whose gastric motility was studied showed similar slight disorders in both the anorexic and non-anorexic children during the previous two or three years. No diseased condition which might explain the anorexia was found by the resident physician, who had cared for them since their entrance into Mooseheart.

(2) Analysis of the records.

In order to obtain as complete information as possible, a number of different measurements were made of the records of gastric activity, including the duration of the activity period, the number of large contractions in the period, the duration and height of individual contractions, and the length of the interval between activity periods. An activity period was measured from the time contractions of 1.0 cm. or more in height began to appear. These measurements were made because it was found that simple inspection or brief measurement of the records did not give reliable information for comparison of the anorexic and non-anorexic groups.

The initial treatment of the data by the computation of averages and ranges showed no marked difference which would clearly differentiate the anorexic from the non-anorexic group, because of the variability of individuals and the overlapping of groups. Newer small sample methods (Fisher, 1930) were used to determine definitely whether any significant differences existed between the two groups. By so doing it then became possible to state the following positive conclusions: The anorexic group had on the average a significantly shorter interval between activity periods and a greater number of contractions in a single period than the control group, both of these measures indicating greater gastric activity on the part of the anorexic children than the non-anorexic children. However, their contractions were found to be on the average shallower than those of the non-anorexic children which indicates that the gastric activity of the anorexic children was less vigorous than that of the control group. In line with this fact is the observation that individual contractions were of shorter duration in the anorexic children than in the non-anorexic children. No difference between the two groups was found in the durations of their activity periods, and in certain measures of the incomplete tetany periods.

If it is assumed that the vigor of individual contractions is the stimulating factor in hunger, the anorexic children with their less vigorous contractions may be thought to have less vigorous hunger feelings. The three different types of explanation of anorexia put forward in the introduction may hold in different types of cases. In cases studied in this paper it is felt that the factor of over-solicitude on the part of adults resulting in poor eating habits was not a factor, as there were seldom more than 2 or 3 adults to 16

children and opportunities for attention were limited. As regards the interfering sensations reported by some authors studying adult patients, the possibility of discomfort and distention on taking food has not been ruled out in the cases observed in this study. In many cases the children with small appetites would eat half a dozen mouthfuls readily, then slowly finish a small meal. It is possible either that unpleasant sensations occurred on slight distention of the stomach, or that with the presence of a small amount of food in the stomach, hunger feelings quickly disappeared. A study of gastric activity and sensations on taking small amounts of food would have been interesting in this respect. In regard to a possible association between the condition of anorexia and a frail type of body build, it was found that the children studied were slender and tended to be underweight. Some children of this body type had good appetites however. It cannot be said what part inheritance played and what part temporary environmental (or growth) factors, including small food intake, played in determining the slender, underweight condition.

Variations from test to test and from one individual to another which occur in both groups, cannot be explained at present, but may be due to such factors as variation in diet and in amount of food intake, variation in amount of exercise, and similar factors. In general, as determined by Fisher's Z test for variance, individual differences were found to be significantly greater than differences between tests on the same individual.

SUMMARY

(1) Thirteen children in a group of 200 (6.5%) were found on observation to have low food intake and moderately or definitely poor appetites.

(2) Records of the hunger contractions showed that children in the anorexic group had a greater number of contractions, a shorter interval between activity periods, and the hunger contractions were less vigorous in height and duration than in children of a control group having good or hearty appetites.

(3) No differences between the two groups were found in the length of the activity periods, or in the length of the incomplete tetany periods or the number of contractions in an incomplete tetany period.

(4) Since the anorexic children are differentiated from the control group by having more rapid, less intense gastric contractions, it may be that their small appetites are due to the lack of hunger sensations. It is also possible that in the anorexic children, the already weak gastric activity is more easily inhibited on slight distention with food, with a resultant small food intake.

I wish to thank Dr. A. J. Carlson of the University of Chicago and Dr. Martin L. Reymert, Director of the Mooseheart Laboratory for Child Research, for kind advice, criticism and help in carrying out the research work. Thanks are also due Dr. Harold Gulliksen for advice on the statistical methods used.

Editorials

IS THE STOMACH AN ESSENTIAL ORGAN?

ONE of the peculiar features about the disturbances which follow the complete removal of the stomach is that these disturbances vary considerably in different animals. Following complete gastrectomy adult dogs show only a mild and temporary anemia of the microcytic hypochromic variety (1). However, a more severe anemia may be precipitated by infection, prolonged diarrhea, pregnancy, or an inadequate diet. It has been shown that gastrectomized dogs are deficient in their ability to regenerate hemoglobin, a deficiency which responds to the giving of iron, but not of liver (2).

When fed a suitable diet gastrectomized dogs maintain their weight, and they may even gain, and they may live out a normal span of life. Such animals show slight rarefaction of the bones, but do not develop degenerative changes in the spinal cord (3). It has not yet been possible to duplicate these results with rats (4). This animal, when gastrectomized, exhibits impairment of nutrition, as reflected in its failure to regain the preoperative weight. A persistent microcytic hypochromic anemia is present, which responds incompletely to the administration of iron. No evidences of cord degeneration have been found, although the bone marrow shows hypoplasia. In the monkey the symptoms of gastrectomy resemble closely those found in the dog (5), whereas in the pig they are much the same as in the rat (6).

These differences may represent true "species differences" in the function of the stomach, or on the other hand, they may merely reflect the degree of success that has been met with in the search for adequate diets for the various species of gastrectomized animals.

Early experience in Dr. Ivy's laboratory with gastrectomized animals emphasized the importance of diet, and in view of this fact dietary factors should be carefully considered before trying to explain differences in behavior after gastrectomy by "species differences." Dietary factors may also account for the differences reported by various investigators in the effects of gastrectomy in animals of one species but different ages. Bussabarger, Freeman and Ivy (7) have reported that gastrectomized "puppies" develop osteoporosis of such severity as to lead to gross deformities of the extremities and to pathological fractures. This condition is ameliorated but not completely corrected by the administration of soluble calcium salts. Petri, Norgaard and Bing (8) reported that their gastrectomized puppies showed marked changes in nutrition and gait, as well as changes in the skin and nervous system. The differences in nu-

tritional state presumably resulting from the diets employed perhaps accounts for the differences in symptoms observed by these workers and by Bussabarger and his co-workers.

The experimental work with gastrectomized animals shows that the stomach cannot be considered an essential organ in the strict sense of the word. However, the stomach is more important in the economy of the growing than in that of the adult organism. It is more important also in the pregnant female than in the male. Proper nutritional care is indispensable in maintaining health in animals without a stomach and probably also in men and women similarly handicapped.

GEORG WOLF

GEORG WOLF died on October 9, 1938, in Berlin, in his sixty-fifth year. He attempted over a period of twenty-five years to provide the medical profession with a safe gastroscope, and he saw his endeavor crowned with success when in 1932 the flexible Wolf-Schindler gastroscope was perfected. Therefore, in my opinion his name belongs with those who have made medical progress in this century, and the medical profession owes him homage.

Georg Wolf started as an employee in the electro-optical department of the large factory of Reiniger Gebbert and Schall in Erlangen where he gained experience in the construction of cystoscopes. Eventually, his sense of independence led him to the opening of his own establishment, located in Berlin between the buildings of the Charité and the large University Clinics in the Ziegelstrasse. There are the best cystoscopes, and other lighted tubes were manufactured.

The first step in the production of a gastroscope was taken in 1911 with the construction of the "flexible" Sussmann instrument. In this work Wolf showed an unusual ability to solve the most complicated mechanical problems. Even yet this instrument with its complicated straightening system, its many screws and levers, and its rotating objective appeals to us as a masterpiece of mechanical ingenuity. However, it became clear to Wolf that the best maker of medical instruments is helpless if he hasn't counsel from the

man who is going to use the apparatus. The Sussman gastroscope proved to be unusable because the conceptions upon which its construction had been based were wrong. After this disappointing experience Wolf became cautious in the choice of his medical collaborators, and he accepted new suggestions only when long preparatory work led him to believe that they were sound. He produced instruments incorporating minor modifications, such as the gastroscopes of Huebner, Hohlweg and Elsner, but only twice did he dare to make a big innovation.

When Hoffmann had shown in 1911 that theoretically it might be possible to look along changing curves Wolf made a gastroscope the tip of which was constructed according to Hoffmann's ideas. This tip could be bent forward and backward through an angle of 180° without interfering with the sharpness of the picture seen at the eye piece. But the instrument was clumsy; it had serious disadvantages and it was never put on the market.

After the construction of my first gastroscope in 1922 it was several years before I came in close contact with Wolf, but after that he decided to collaborate with me. His confidence in my suggestions was great, and I had to be careful in my letters for fear that he might carry out minor suggestions without delay. When he built the first flexible gastroscope he was so enthusiastic about it as a mechanical triumph that it took me a long time to convince him that it was not practical and that absolute flexibility was not desirable. What I wanted was some stiffness and elasticity and, in the upper portion of the tube, rigidity. In the five years from 1928 to 1932, Wolf made six different gastroscopes. Eventually he followed my advice and produced the beautiful instrument of 1932, the one which has made gastroscopy a safe and practical diagnostic method.

Georg Wolf lived long enough to see the triumph of our instrument throughout the civilized world. Until the end of his days he kept working on improvements and additions. He was the soul of his factory. In the last decades he had no real competitors in his field. He was a quiet, heavy man, with narrow, extremely sharp looking eyes. His home life was happy, and he was agreeably sentimental. He spoke with a "Berliner" accent and was a true child of this metropolis, the inhabitants of which so often excel by their cleverness and indefatigable industry. His collaborators and friends will not forget his personality, and gastroenterologists must never forget his name.

Rudolf Schindler.

THE DEATH OF PROFESSOR BOAS

SIR ARTHUR HURST, in writing to the British Medical Journal (1:1184, 1938) commented on the fact that Professor Boas, who was one of the founders of gastro-enterology, died in Vienna, March 15, 1938, at the age of eighty. He began his career as an assistant to Professor Ewald at the Augusta Hospital in Berlin in 1885. Working with Ewald, he devised the test breakfast which is so well-known to us all today.

Boas was a brilliant clinician and had the reputation of being the foremost gastro-enterologist of Europe. His textbook, "Diseases of the Stomach and Intestines" was popular for years, and it passed through many editions. It was translated also into several

languages. We owe to Boas the method of watching the stools for occult blood in diseases of the stomach and bowel. In 1898 Boas founded the "Archiv für Verdauungskrankheiten" and in 1920 he founded the German Gastro-enterological Society.

With the advent of National Socialism, Boas had to leave Germany and was fortunate to receive an invitation to continue his work in Vienna. When Vienna was taken over by the Nazis, Boas realized that the end of his working life had come. Having no desire to submit to further persecution and impoverishment, he took an overdose of veronal.

W. C. Alvarez, Rochester.

A LOCALIZED PATCH OF GONORRHEAL PERITONITIS WITH SYMPTOMS SUGGESTING ACUTE CHOLECYSTITIS OR APPENDICITIS

ONE of the rarer causes of acute abdominal pain is a patch of localized peritonitis due to invasion by the gonococcus. Doubtless in many of these cases the appendix is removed, and unless the surgeon immediately faces the fact that this organ looks fairly normal, and makes a careful and extended exploration of the abdomen, the real cause of the pain and tenderness and abdominal rigidity is not found.

In a recent article, S. J. Sullivan (J. A. M. A., 110: 1342, 1938) reported a remarkable case in which the surgeon operated on a married woman of forty-four who was seen with typical symptoms and signs of acute appendicitis and a white count of nearly 21,000 cells. At operation an acute suppurative appendicitis was found, but in addition there were slightly inflamed tubes, many petechial hemorrhagic areas along the last ten feet of ileum, and a little free fluid in the abdominal cavity. When cultures showed gonococci, the husband confessed that he was just coming down with gonorrhea contracted seven days before the operation. *Four days* before the operation he had had one act of intercourse with his wife. Since the wife maintained that she had had no other sexual contact, one must assume that gonococci were able to pass from the vagina into the peritoneum and produce an acute virulent infection *within four days*.

W. C. Alvarez, Rochester.

ERROR

In Prof. B. P. Babkin's Editorial in the January issue entitled "Testing of the Secretory Activity of the Gastric Glands in Man by Means of Histamine and Insulin" the figures for the experiment of April 29 were erroneously printed in the experiment of May 3, and vice versa. Book Reviews

Le Systeme Nerveux Vegetatif. By J. Tinel. Masson et Cie, Paris, 1937, 847 pages. Price 160 fr.

THIS is a monumental work on the vegetative nervous system. It covers 847 well-written pages in which few words are wasted. Seldom has the reviewer been more impressed by the way in which the field of science has been widening than when he contemplated the size of this volume on but one part of the nervous system of man. And even then it is not large enough, because when the reviewer looked closely at some of the chapters devoted to parts of the subject with which he is familiar, he was disappointed to find them so short and inadequate. Some of the inadequacy is due partly to the Frenchman's usual tendency to quote only from French authorities. A French writer seldom seems to know much of what's going on in the United States; he may know a little of what's going on in England, but if he knows of any good work coming out of Germany, he doesn't say much about it.

Actually, however, in view of the richness of the feast that is set before us in this book, it is hardly fair to cavil and to ask for more. An American would, of course, like to see some report of the large amount of work done on the medical side of the problem by George Brown, Adson and other Americans.

The book is well illustrated with 306 plates. Tinel starts out with an extensive description of the anatomy and histology of the vegetative nervous system. He then goes on to speak of the hormones that arise in this system, and the way in which the nerves respond to the administration of drugs. There are many chapters on the involuntary nerve supply of various organs and various parts of the body. Very curious are the photographs showing that nevi sometimes follow the segmental distribution of sympathetic nerves. There is much on the new and interesting subject of autonomic nerve centers in the diencephalon and the cortex.

There is much on the diseases and disturbing symptoms which are produced by abnormalities in the sympathetic nervous system, and this part of the book is perhaps the most nearly complete and the most valuable. It would doubtless well repay careful study. As is well known, the Frenchman is particularly happy and versatile when he is describing new syndromes.

It is probable that when more study has been made of these syndromes due to disturbances in the autonomic nervous system, more sympathy will be accorded many of the patients who are now looked upon as merely "neuros."

There is an interesting section on the causalgias, those miserable pains which persist even after all the known nerves to a part are sectioned. On page 617, Tinel speaks of cases in which pain not relieved by section of the nerve proximal to the lesion is relieved by section of the nerve distal to the lesion. This is a good sample of the puzzles which one encounters in this field.

There is much interesting material on the comparatively new science of studying autonomic reflexes. One can sometimes locate lesions by noting the behavior of pilomotor nerves, sweat glands, and even the erectile

tissue around the nipple. There is a discussion of the interesting problem of the nature of the sensory side of the autonomic system, and there is a final section on surgery and the use of drugs.

As the reviewer stated before, he wishes that Dr. Tinel had spent more effort in bringing the last section on surgery up-to-date. For instance, there is only a page and a half on resection of the presacral nerve, which is hardly enough space in which to discuss this often helpful operation, together with the indications for and against its use. Few references have been supplied. For a book of this size the author might well have supplied a bibliography of 700 titles. Actually, he gives less than two pages and a half to a bibliography in which he lists only a few outstanding articles. On the whole, however, one must compliment Dr. Tinel on the completion of a tremendous task, and one must thank him for bringing together in one place such an enormous amount of information.

W. C. Alvarez, Rochester, Minn.

The Horse and Buggy Doctor. By Arthur E. Hertzler. Harper and Brothers, New York, 1938, 322 pages. Price \$2.75.

WHEN a poor farmer's boy works his way through college and makes of himself a good physician, that is not news; it has been done too many times before. When a young doctor works day and night, covering a big territory in a horse and buggy and serving devotedly a large community, again, that is not news. When the young physician soon saves enough from a poor type of practice to take his family to Europe and spend two years making himself an accomplished anatomist and pathologist, his behavior becomes worthy of comment, and when in his later years he writes a delightful book of memoirs which is promptly chosen by the Book of the Month Club, his doings become decidedly newsworthy.

Actually, every physician, and particularly every physician past fifty years of age who has done general practice in the country, will delight in this book, which presents a picture of that heroic type of practice which was common before the advent of the automobile, the concrete highway and the hospital. It is the picture of a doctor driving long distances across the prairies by day and by night, in all sorts of weather, in rain storms and blizzards. Often at the end of a long journey there was no one to greet the doctor or let him in to warm his frozen hands, because the patient, some psychopathic woman, had gotten over her hysterics and gone to sleep. And then the poor doctor had to drive the long weary way home without a cent because "he hadn't rendered any service." But again there often was a patient with an intestinal obstruction or an acute appendicitis or an empyema, and then the operation had to be performed on the kitchen table, perhaps by lantern light and with the hired man giving the anesthetic. For years Hertzler kept his promise to his father that he would answer every call even when it came from those who couldn't or wouldn't pay.

Hertzler tells the story of the building of his first little hospital with the bitter jealousies and enmities which it aroused. After years of struggle and expense he was glad to give the place away for one dollar. His big reward was the knowledge that he had built an institution of great value to the community.

All through the book one finds much homely wisdom and much about the psychology of medical practice and the folly of trying to cure with medicine or surgery disease that is due to dissatisfaction, frustration, sexual starvation and unhappiness. The world has been made a better place by the work of men like Hertzler with their rugged honesty, good "horse sense," dry humor, and devotion to the service of their fellow men.

If in these changing times the medical profession had hunted for a public relations counsel to build up among the lay men and women of America a better appreciation of the type of public service rendered by the old-fashioned type of physician, it could hardly have found a better man than Dr. Hertzler. I doubt if any layman, no matter how bitter he might feel toward the medical profession because of some unfortunate happening, could read this book without concluding as Robert Louis Stevenson did, that the physician tends to stand above the common herd—a man of courage, devotion, honesty, ability and resourcefulness; one who thinks first of service to his fellow man and only secondarily of his pay.

The reviewer has only one sorrow in regard to this book, and that is that his father who, like Hertzler, sometimes swam rivers in flood and often had to trust to his old horse to find the way through storm and darkness, didn't live to read this Odyssey. How he would have loved it!

Walter C. Alvarez, Rochester, Minn.

Clinics on Secondary Gastro-Intestinal Disorders: Reciprocal Relationships. By Julius Friedenwald, Theodore Morrison and Samuel Morrison. William Wood & Company, 251 pages, 1938.

THIS volume undertakes to elucidate, for the medical and the general practitioner, the reciprocal relationship between organic diseases of the alimentary tract, with distant visceral manifestations, as well as the relationship between organic diseases of other viscera with associated predominant gastro-intestinal symptomatology.

The preface which states that "no such text is available in English" is hardly correct, for many classical and scientific papers and monographs have discussed such dual relationships as coronary artery disease with essentially only abdominal symptoms; renal calculus with gastric manifestations; tabes dorsalis with only alimentary disturbances. And who today is unfamiliar with the "gastric mask" of gall bladder disease?

Yet, though the subject is amply discussed in chapters of modern textbooks and in individual monographs, no one but the authors of this new book have attempted to correlate and collect the entire matter as a well-rounded and complete clinical treatise.

The gastro-enterologist knows well the confusion between the abdominal symptoms and underlying distal pathological disease. The medical student and the general practitioner are liable to have under-

estimated this reciprocal relationship and for them therefore, and for all of us, this volume is valuable.

The text is readable and fluid, the content treated in a direct clinical style and manner of the old masters. The literature is modern in the extreme, the periodicals have been combed for representative illustrations of points made. The style is good.

The newer statistical method of representing the incidence of disease and of portraying the frequency and order of certain symptoms is missing. The "business machine" method of presenting clinical facts is apparent nowhere in this volume. Old-fashioned clinical description is relied upon and case histories dot the book and clearly illustrate the bed-side observations made.

Very few adverse criticisms of the volume can be made. We would wish for a more outspoken opinion on the subject of chronic appendicitis. There should no longer be a need for straddling the fence and apologizing for those who hold to the existence of this flimsy diagnosis. Gastritis is again a bit loosely handled, particularly with reference to chronic nephritis, when actually the existence of chronic gastritis as a clinical condition needs much more evaluation.

The chapters on the endocrines and their relationship to gastro-intestinal symptoms are well put, nor is the value of endocrine therapy given undue prominence or mistakenly overestimated. In fact, throughout, the therapy is rational and sound and never overstated.

One regrets again the somewhat old-fashioned treatment of the subject of the so-called gastric neuroses. While the psychic approach is truly well-registered, one sees the hand of the old-time experienced clinician in such terms as "gastralgia nervosa," "hydrochlorhydria" (a term no longer tenable), "gastro-intestinal neurasthenia," etc. Unfortunately, the newer psycho-analytic, or Freudian approach is quite missing and the recognition of such common complexes as the suppression neuroses, anxiety states, the hysterias and the substitution phenomena are insufficiently elucidated.

The volume is a good readable text that portrays vast clinical experience, sound judgment, and an extensive knowledge of the past and of very current literature. It is highly desirable literature for all those actively engaged in the study and the practice of internal medicine.

Triumph Over Pain. By René Fülöp-Miller, translated by Eden and Cedar Paul. The Bobbs-Merrill Company, Indianapolis, New York; 407 pages.

RENÉ Fülöp-Miller has done a splendid piece of work based obviously on much research through rare journals and archives. There are some chapters on pain in general which physicians may want to skip, but they will not want to skip a single paragraph of the fascinating story of the discovery of what is perhaps man's best gift to man: a story of envy and bitter jealousy, of ruin for three out of four of the contenders for immortality, of disgraceful spinelessness on the part of the President of the United States, and of thanklessness on the part of the public.

Morton, the man whose genius and persistence unquestionably gave surgical anesthesia to the world, died broken hearted and almost out of his mind. He

PEPTIC ULCER PAIN RELIEF

FROM U. S. P. GELATINE (KNOX)

... according to Recent Clinical Study

Frequent "concentrated" feedings of pure U.S.P. Gelatine have, in the experience of Windwer and Matzner,* given prompt symptomatic relief in 90% of a series of cases of peptic ulcer without the use of drugs or chemicals.

The advantages of this clinically tested peptic ulcer regime are, quick relief from pain, no untoward effects from cumulative, irritating drugs, freedom from alkalosis, and no undue interference with digestive functions.

Knox Gelatine is 100% pure U.S.P. Gelatine—85% protein in an easily digestible form—contains no sugar and should not be confused with factory-flavored, sugar-laden dessert powders. "Concentrated" feedings of Knox Gelatine are easily prepared in appetizing form and are well tolerated. Send for recipes.

A simple formula for the preparation of concentrated Knox Gelatine

CASE I—FEMALE, 74

Uncomplicated gastric ulcer first demonstrated by Roentgen rays in 1931. Diet and alkalies afforded little relief. Accompanied by loss of weight. Repeated X-ray studies in 1936 and 1937 showed no improvement. She was placed on a diet gelatin regime in November, 1937. Relief immediate. Gained weight. Roentgen studies in April, 1938 showed no demonstrable ulcer.

feedings, useful in peptic ulcer is, stir quickly one envelope (approximately 8 grams) of Knox Gelatine in $\frac{3}{4}$ of a glassful of drinking water and have patient drink quickly before it "sets" or gets lumpy.

was importuned by creditors, and hounded to his death by the fiendishly clever and persistent persecutions of Jackson. Jackson, a chemist, doubtless gave Morton some helpful hints, but he didn't have the interest or courage to work out the problems of using ether, and when Morton went ahead, he, Jackson, so feared failure and trouble that he would have nothing to do with the project. Later, when Morton succeeded, Jackson claimed that he was the discoverer and that Morton was only his assistant. When this was disproved Jackson decided that if he couldn't have the credit, at least he'd see to it that Morton didn't get it, and with this spiteful motive, he spent the rest of his days hounding Morton and ruining him professionally, financially, and every way. Each time that Congress was about to give Morton an award, Jackson blocked it by hunting up the bringing forward as the "real discoverer" either Wells or Long, men who, it is true, had operated under anesthesia before 1846, but who had soon become so discouraged that they did not publish their work.

Eventually Jackson became so poisoned by his bitter thoughts that he went insane; Wells went insane and committed suicide in prison; Long died disappointed and unhappy, and Morton almost lost his reason. His death followed the shock of hearing that Jackson had broken into print again with new calumnies.

Doubtless the devoted admirers of Wells and Long will feel inclined to accuse Füllöp-Miller of bias, but anyone who with open mind will take the trouble to read the statements of Dr. Warren, to whom Morton went with his discovery, and of the other physicians at the Massachusetts General Hospital who saw the first operations done there under ether anesthesia will be satisfied that the man who gave anesthesia to the world was Morton. He it was who went on etherizing animals and breathing the drug himself day after day until he felt he could safely try surgical anesthesia in the hospital, and he it was who talked Dr. Warren into trying the new substance on patients. He it was who persisted until knowledge of the discovery spread over the civilized world.

Morton has been blamed by many for patenting his discovery and for trying to make some money out of it, but on examining the record, one is inclined to forgive him entirely. Almost from the start he granted to hospitals and to the medical department of the U. S. army and free use of the method. It is the American people who should feel ashamed because their government, after disregarding and infringing the patent it had granted to Morton, held up the compensation that was about to be granted him with the claim that since the patent had been infringed without contest, it had lost its value and was therefore not worth paying for! Actually, it appears that it was largely patriotism which, at the beginning of our war with Mexico, kept Morton from fighting for his rights. The pinch-penny arguments of the lawyers so impressed Pierce that he advised Morton to borrow the money to come to Washington and file a friendly suit against some government hospital. Then, with the title to the patent cleared, he, Pierce, would promptly sign the bill to remunerate Morton and right the wrong done him.

Unfortunately, when Morton reluctantly did as he was told, everything went wrong. The suit was contested, and everyone, including the medical profession, promptly began to hurl abuse at Morton. Pierce, ap-

parently without backbone or decency, let Morton down after getting him into the awful mess, and soon Morton found himself stripped by angry money-lenders, turned out of his home, and too ill and unhappy to work at his profession.

What a sorry story it is and how much wiser Morton would have been if he had invented a machine for killing and mangling young men, by the hundred thousand! Then he would have become a millionaire, and at his death a great mausoleum would have been built over his ashes.

Füllöp-Miller's book should be read by all research workers if only to serve as an awful warning to keep out of fights over priority of discovery. Let every man stick to his work; let him publish when he is sure of his results, and let him leave to posterity the decision as to who it is that deserves credit. Usually the world gives most credit, not to the man who saw dimly or saw first, but to the man who hammered away until he made everyone take notice of, believe in, and adopt and use the particular idea or invention. Often the world first ignores, then it ridicules, then it accepts. Finally there appear little men who, after much rummaging in libraries, come forth to prove that credit should be taken from the man who is being honored and given to someone long since dead.

Der Magenkrebs. By Prof. Dr. Med. Georg Ernst Konjetzny, O.Ö. Professor der Chirurgie der Hansischen Universität, Direktor der Chirurgischen Universitätsklinik zu Hamburg. Cloth. Pages 286, including 155 illustrations, 20 tables, and an extensive bibliography. Stuttgart: Ferdinand Enke, 1938.

IN this monograph Konjetzny summarizes thirty years of study of the problem of gastric carcinoma. His earlier work is well known and has thoroughly established his position as one of the foremost authorities on the subject. The present monograph reaffirms the views previously published, coordinates the data, adds much new material, and presents a complete picture of our present knowledge of the genesis of gastric carcinoma and its clinical application. The book will be welcomed by all those interested in the various aspects of the problem.

In the introduction the author calls attention to the well-known fact that the stomach is the organ most frequently affected by carcinoma and that today the majority of the patients so afflicted come to the internist and the surgeon too late for cure. In the battle against gastric carcinoma only two possibilities exist: Prophylaxis or early radical surgical treatment.

Under the heading of etiology Konjetzny discusses first the role of heredity and concludes that cancer as such is not inherited, only a certain tendency or organ disposition. External conditions are thought to be the more important factors. The theory of contagiousness and infectivity seems disproved, as does the Cohnheim concept of carcinoma arising from embryonal cells left over after the development of the fetus and its organs. Trauma is considered significant only as it relates to the sequelae of corrosion of the mucosa, as in acid or alkali poisoning. Virchow's theory of carcinoma as a resultant of local disease processes is accepted, and a large section of the monograph is devoted to the thesis that "the chronic inflammatory conditions which demand greatest consideration as the basis of gastric

A MORE DIRECT ATTACK ON

PEPTIC ULCER

Published reports demonstrate that the beneficial effects of Synodal are usually manifested after a few injections. Aside from the relief of discomfort, there is good evidence that Synodal may also exert a healing effect upon the ulcer. The customary dose of 6 cc. (containing 1 grain of emetine hydrochloride) is administered every third day for three weeks, after which one injection per week is sufficient. The maximum number of injections in one course is ten, and an interval of from six to eight weeks should elapse if a second series is required.

HOW SUPPLIED: Synodal is available in ampules of 6 cc., boxes of 5 and 25.

Detailed literature on request.

carcinoma formation are: The chronic gastritis with its sequelae and the chronic gastric ulcer." Konjetzny's life work indeed has been the study of the relationship between chronic gastritis, benign ulcer, and carcinoma. He views gastritis as the basis for both ulcer and carcinoma. In his experience gastric carcinoma is always associated with a pronounced chronic atrophic or atrophic-hyperplastic gastritis. Carcinoma never develops in a normal gastric mucosa. The essential process in the gastritis-carcinoma relationship is not the inflammation but regenerative changes in the epithelium constantly induced by it. The complete transition from pure gastritic changes to polyp formation and carcinoma is described in detail and well documented with convincing illustrations. The carcinomatous development begins in the cells over a broad area of the mucosa and hence is multicentric in origin. The subject of carcinomatous transformation of a benign ulcer is discussed at length. The conclusion is reached that it is not possible by clinical methods alone to make such a diagnosis. Pathologic evidence, especially the histologic, is more definite, but here also difficulties exist. The diagnosis cannot be made on the basis of any single pathognomonic finding but rather by a careful analysis of all the evidence. Carcinoma may develop in the edge of a benign ulcer or adjacent to the ulcer but independent of it, related not to the ulcer but to the gastritis, to which Konjetzny attributes both the ulcer and the carcinoma. With regard to the differentiation of ulcer-gastritis and carcinoma-gastritis Konjetzny says that in ulcer the gastritis is usually more acute and localized to the antrum whereas in carcinoma the gastritis tends to be more chronic and to involve larger areas of the gastric mucosa. There is, however, no specific or fundamental difference.

Among the macroscopic forms of carcinoma Konjetzny distinguishes the following types:

1. The pronounced mushroom or polypoid tumor developing chiefly into the lumen of the stomach.
2. The ulcerated dish-like growth with clearly defined borders.
3. The ulcerated carcinoma without a definite wall or a sharp border and with infiltration of the gastric wall beyond the edge of the ulcer.
4. The definitely diffuse type with gradually decreasing thickness of the gastric wall from pylorus to cardia, the borders of the tumor not being definitely palpable, or with thickening of the entire gastric wall.

The histologic types are variable and are not to be correlated with the macroscopic. The prognosis for surgical treatment is, on the whole, much better in the first and second groups than it is in the third and fourth. A histologic classification is not of much prognostic value.

Effective therapy depends first, upon early examination and second, upon gastric resection of all early carcinomas and indeed of all cases of polypoid gastritis, this being definitely a precarcinomatous, if not already carcinomatous, condition. All patients with digestive symptoms should report promptly to the physician, who should use all available diagnostic means necessary for the establishment of a definite diagnosis. The history, physical examination, and the gastric analysis are not sufficient but should be combined with a search for occult blood in the stool and with careful roentgenologic and gastroscopic examination. These methods are most valuable. The author

is opposed to exploratory laparotomy as a diagnostic procedure because the methods mentioned are reliable and also because small carcinomas often cannot be palpated even when the surgeon has the stomach in his hands. When a portion of the stomach is held in suspicion clinically, it should be resected. Resection should be carried out in almost all cases of carcinoma even though a very radical operation is required, such as complete gastrectomy or partial gastrectomy combined with partial colectomy. The chief contraindications to resection are *definite, proved*, distant metastases or extensive carcinomatous peritonitis. Significant palliative effects have been obtained even when Krukenberg tumors had to be removed in addition to the gastric lesion. In spite of the fact that Hitzberger and Markler found thirteen-year cures in only two per cent of 272 patients with gastric carcinoma, Konjetzny feels that undue pessimism is not warranted, even in the young. The longest cure observed in the Breslau Clinic was that of a man operated upon when thirty-one years old and followed for twenty-one years. With earlier diagnosis and earlier radical resection better results should be obtained.

Vitamin B₁ and its Use in Medicine. By Robert R. Williams and Tom Douglas Spies, N. Y., The Mac Millan Company, 411 pages, 1938.

IN the past few years so many contributions to the subject of vitamins have accumulated that many physicians have expressed frankly their inability to keep "au courant." This has been true particularly in the case of Thiamin Chloride, (as Vitamin B₁ has been tentatively named). This book has been timely written and presented and will come as a welcome friend to those frantically striving to maintain their heads above the tidal wave of vitamin researches.

The authors have set as their goal the painstaking compilation of all known facts—as well as many unproven concepts—of this vitamin. The book has been written in two parts, of which the first part (120 pages) will interest the clinician mainly. Here he will find listed the many conditions in which Thiamin has been used. Often the material is presented in abstract form permitting the reader to exercise his own critical judgment but at times the authors express their own views. Thus in the chapter on prevention and treatment we read this statement—"Irrespective of predisposing conditions and co-existing diseases, the authors consider the manifestations of Vitamin B₁ deficiency as Beriberi."

This concept may prove startling to those physicians who view Beriberi as a distinct and often serious clinical entity. It may be difficult to reconcile this viewpoint with the clinical uses of this vitamin. However the authors are well aware that "the use of Vitamin B₁ in medicine" is in the process of evolution. Much will be modified even in the next few years.

Especially illuminating is the collection of data on the pathology and pathological physiology of Vitamin B₁ deficiency in animals and humans. In the short space of twenty-two pages is grouped an enormous amount of material culled from all types of scientific literature, literally from all parts of the world. Just to read this chapter alone is a saving of many hours of arduous library work.

Many tables of foods and diets and their B₁ content

For becalmed *peristaltic waves*

In atonic constipation, slow, weak peristaltic waves considerably retard the movement of residue through the intestines. Desiccation and impaction sometimes occur. Definite relief is usually afforded by salines.

Sal Hepatica

resembles, in its action, famous natural mineral spring waters. It helps to bring to the intestines sufficient *liquid bulk* to gently stimulate peristaltic waves and thus rid the colon of undesirable waste. Its mineral salts combat gastric hyperacidity. Sal Hepatica also stimulates bile flow from both liver and gall bladder. Increasing steadily is the professional recommendation of Sal Hepatica . . . Samples and literature upon request.

*Sal Hepatica Flushes the
Intestinal Tract and Aids Nature Toward
Re-establishing a Normal Alkaline Reserve*

BRISTOL-MYERS CO., 19-NN WEST 50th STREET, NEW YORK, N. Y.

are given not only in part one (pp. 112-118) but also in part two (pp. 236-240). These will be of great value in modern dietetics as most if not all of the older tables contain many inaccuracies.

The inclusion of a short note on the toxicology of Vitamin B₁ will be appreciated by many clinicians who have repeatedly inquired about this problem. Death can be brought on by massive doses in the experimental animal and the authors express the therapeutic safety as follows—"The ratio of the effective therapeutic dose to the minimal toxic doses is between 1:7,200 to 1:36,000."

Part two contains the historical and experimental data. The busy practitioner may find little to guide him in his clinical problems, but the student of medicine and the chemist—and many others—will experience a real joy at the concise and yet complete collection of data about Vitamin B₁.

From this part of the book will come the stimulus to solve many of the remaining problems of Thiamin Chloride; the relation to thyroid activity; the role it plays in the function of the liver; the relation of thiamin and nicotinic acid to the carbohydrate metabolism, etc.

The authors are acutely aware of the fundamental nature of their work in this field. In an excellent recapitulation their keen insight is focused in well balanced statements in which enthusiasm and conservatism go hand in hand. Almost prophetic is their statement that "it seems likely that the Vitamin B₁ requirement of all living things will turn out to be essentially alike in terms of molecules of the metabolite which are converted into energy."

The authors may well be pleased. They have written a book which has been needed urgently by the medical profession. No one interested in Vitamin B₁ can do without it. Nowhere else can be found all of the present knowledge of Vitamin B₁.

Martin G. Vorhaus, New York City.

Food, Health and Income. By J. B. Orr. London, Macmillan and Company, 1937. Price \$1.00. (Second Edition).

EVERY student of mass dietetics will want to study this little volume, since it brings much of the information that is needed before men can decide just where to put the dividing line between a diet which maintains life and that which insures health, good growth, and optimum resistance to disease.

As Dr. Orr points out, conditions in England have been improving, but still half of the population must live on so small an income that it is doubtful if parents can properly feed their children. Actual tests have shown that an improvement in the diet of children of the poor will result in improved health and increased growth. The diet of 4,500,000 people in the United Kingdom appears to be deficient in every constituent examined. The 9,000,000 in the next higher economic group get enough protein but too small a supply of vitamins and minerals. Another 9,000,000 live on what appears to be a deficient diet.

Curiously, the consumption of bread and potatoes is about the same in the poorest and the richest homes. With increased income an increase is noted in the consumption of milk, eggs, fruit, vegetables, meat and fish. A decrease is found in the consumption of condensed milk and margarine.

Attaining Manhood. By George W. Corner. Harper & Brothers, New York, 1938, 67 pages.

MANY men and women have tried to write a little book to give instructions to children in matters of sex. Few could approach the problem with greater wisdom than that possessed by Doctor Corner. As everyone knows he is one of the world's ablest students of the anatomy and physiology of the reproductive processes in the body. He also has a fine command of the English language, and is one of America's authorities on the history of medicine. This little book was written primarily for the instruction of his own boy.

Naturally with Doctor Corner's training one would expect him to devote most of the book to an explanation of the anatomy of reproduction and the development of the ovum and the fetus. If there should be any later editions, Doctor Corner will probably add more material on the problems of sexual behavior. The book is sound, and it can be recommended to parents who want something to give to their children.

The Spivack Gastrostomy. By Frank H. Baehr, M.D. and Stanley Frehling, M.D., Westfield, Massachusetts.

THE authors are extremely enthusiastic about the possibilities of this operative procedure. The article presents one case report where the technical result was satisfactory. The preparation of a tube made from a portion of the anterior gastric wall and brought out through the abdominal wall is ingenious. The concomitant formation of a valve-like structure at the junction of this tube and the stomach proper, acting so as to prevent the regurgitation and leakage which has been the greatest problem to the surgeon is important.

The paper itself has an excellent description of the operation and is accompanied by well-prepared and clear drawings of the entire procedure. Whether or not the procedure should be adopted more uniformly remains to be seen. The satisfactory gastrostomy has not as yet been perfected, and all avenues should be explored in an endeavor to obtain perfection.

Henry H. Lerner, New York, N. Y.

Cabot's Physical Diagnosis. By Cabot, Richard and F. Dennette Adams. 12th ed., Baltimore, Wm. Wood & Company, 1938, 846 pages.

THE thousands of physicians in this country who learned much of what they know about diagnosis from Cabot's book on the subject will welcome as an old and deeply respected friend this twelfth edition. The book has grown greatly in size and completeness since it was first issued in 1900. As Dr. Cabot says, during the earlier years it was a one-man book, based largely on his own experience, but now the field of medicine has become too great for any one man to be an expert in all specialties. Hence it is that in this edition Dr. Cabot has appealed for help to a large group of physicians, many of whom work with him at the Massachusetts General Hospital. The book has been entirely revised and rewritten. New illustrations have been used, and there is an increase of 50 per cent in the material without an increase in the price of the book.

"Water Balance" in Constipation Control

The water content of the bowel determines normalcy. Thus:

Excess H₂O—is present in diarrhea

Deficient H₂O—is present in constipation

Mucilose, by influencing "water balance," brings about a more normal condition in the fecal content.

Therefore, prescribe Mucilose to help restore normal bowel function and so relieve the alternating symptoms of constipation and diarrhea often associated with spastic colitis.

MUCILOSE

offers a hemicellulose (vegetable gum) prepared by a special process from the *Plantago loeflingii*. It affords symptomatic relief in colitis and constipation by holding water in the feces, and thus increasing responsiveness of the physiologic mechanism of peristalsis.

Mucilose is available in two convenient, palatable forms—**Mucilose Granules** and **Mucilose Flakes**.

Mentality and Homosexuality. By Samuel Kahn. Boston, Meader Publishing Company, 249 pages. Price \$3.00.

EVERY so often the internist will run into a case in which a woman's nervousness proves to be due to the fact that her marriage is going on the rocks, and this because of the homosexuality of the husband. Commonly, the physician will not get the story, and then, of course, he will not be able to help the patient with her mucous colitis, her nervous breakdown, or her nervous regurgitation. But if he is sufficiently interested in the life tragedies of his patients to get the story, what is he to think and what advice is he to give?

To most normal men and women, the subject of homosexuality is so disgusting that they refuse to face it or to learn anything about it, and even the psychiatrist, the penologist and the police judge usually display woeful ignorance in regard to the problem.

The only way in which to learn about homosexuality is to study homosexual persons. No amount of theorizing will take the place of the information that can be gained through getting the confidence of these people and talking to them sympathetically about their problems. A man would have to be hard-hearted indeed not to sympathize with the sadness or horror which comes over some of these people when they discover that through some miserable prank of nature they are to be denied the greatest comfort that can come to a human being and that is to have a mate and home and children. To understand the tragedy of the situation, one need only read "The strange confession of Monsieur Mountcain," or "The Invert, by Anomaly," or a story called "Death comes on an Atoll," published in the *Atlantic Monthly* some three or four years ago.

One of the best places in which to meet many homosexuals and to get to know them well is a big penitentiary, and Dr. Kahn, who has been a prison physician and psychiatrist, has taken advantage of his opportunities to write an interesting and helpful book on these people and their problems. It is doubtful if any open-minded person can read this book without coming to the conclusion that these people are primarily to be pitied, and that they should not be hounded savagely by the law. Neither should our laws be so designed as to help the band of blackmailers who now prey on homosexual men in every large city.

Kahn shows that most of these people were born handicapped, in that they come from families in which there is much insanity and degeneracy. Although some of these people are gifted and able, especially in the field of art, many are of low mentality, and easily influenced by the suggestions of others. Because of this they are easily led astray by criminals, and taught bad habits such as the use of morphine and cocaine. Many doubtless take drugs to help in the forgetting of their sorrows.

The anthropologist and the collector of underworld argot will be much interested in the many special names which these people give to the various types of homosexual persons, both male and female. Many men know what a "fairy" is, but few could define a fag, a brilliant, a bulldiker, a red top, a fish, or a queer bird.

Very enlightening are the love letters which Kahn publishes. Having been sent from one homosexual prisoner to another, they show something of the psychology of these people. Obviously, their type of love

is just as vivid and compelling to them as is that of any heterosexual person to him or her.

This book should be in the library of every penologist and psychiatrist. It is to be hoped that some day we Americans will be sufficiently civilized so that our laws in regard to these people will either be taken off the books or else made more merciful. Today they are inspired by ignorance, savagery, dislike and abhorrence; some day they must be based on knowledge, and sympathy for the unfortunate. Once mentally unbalanced persons were chained up and treated like wild beasts; today most of them are cared for mercifully. About the only psychopaths who are still treated savagely are the paranoiacs who commit murder and the homosexual men. For some unknown reason, homosexual women are not annoyed by the law, although their numbers appear to be much greater than are the numbers of homosexual men. Perhaps women too would be treated brutally if women had made the laws.

Medico-legal Aspects of the Ruxton Case. By John Glaister and James Brash, Baltimore, William Wood & Company, 1937, 284 pages. Price \$6.00.

THIS is a most remarkable story of the work done by a group of physicians, anatomists, and other medical men at the University of Edinburgh in an effort to establish the identity of two bodies, so hacked to pieces and disfigured that no identification could possibly be made by relatives. The murderer was a physician who killed his wife and her maid. He then cut the bodies to pieces, removing muscle from bones, dissecting the skin off the face, and removing the fingers so as to get rid of the prints. He then threw the remains into a ravine some miles from the scene of the crime, and there they were found after a couple of weeks.

In order to produce a corpus delicti, anatomists put the scraps of the bodies together and established the fact that they belonged to two women. In each case they superimposed a photograph of the head and face over the skull and showed that the fit was good. They checked many details of teeth, of foot size, as compared with the victims' shoes, and so forth. They estimated the standing heights of the two bodies, and altogether, they did a tremendous amount of work, in which modern science played a great part. In the end they had no difficulty in convincing a jury that the mangled remains represented the bodies of the doctor's wife and the maid.

The book is well illustrated, and it doubtless will constitute for the next hundred years an invaluable text for all medico-legal workers. Although not particularly gastro-enterologic in its interest, it will be of great interest to physicians in every specialty, and to all those who are interested in the behavior of the psychopath and the murderer when he happens to be a physician. There is a good summary of similar famous cases in medico legal literature.

Anal Fissure, an Evaluation of Treatment with Oil Injections. By George S. Speare, M.D. and Roy E. Mabrey, M.D., Boston.

COMMENCING with a clear concise description of the anatomy of the anal canal, the article goes on to discuss the etiology of fissures. The authors state that fissures are the result of infections of abnormally

Cloth and Home-Brewed "Remedies"

Homespun cloth still has its quality appeal but home-brewed remedies are done with. Advanced methods in the art of pharmacy have replaced the rule-of-thumb of the kitchen chemist.

An impressive example of modern exacting compounding is Loraga, in which so fine an emulsification of mineral oil and agar is attained that thorough mixing with the intestinal contents is assured and leakage obviated. A pleasing taste is achieved without artificial flavoring. Absence of sugar, alcohol and alkali in Loraga makes it suitable for all age periods.

Loraga contains no added laxative ingredients. A fine mineral oil emulsion, indeed, in the treatment of the costiveness of children and adults when no active peristaltic stimulation is indicated. You can obtain a trial supply of Loraga by writing for it on your letterhead.

WILLIAM R. WARNER & CO., INC., 113 West 18th Street, New York City

deep crypts with resultant ulceration of the crypt wall or its tearing by the passage of hard feces. There are two possible results of an infected crypt. If the lumen of the crypt is directed downward along the wall of the anal canal between the mucosa and the sphincter, a fissure is formed. On the other hand, if the lumen of the crypt is directed away from the anal canal toward the fibres of the internal sphincter, the infection breaks through into the tissues of the ischio-rectal fossa and forms a peri-anal abscess resulting in an anal fistula.

The symptom complex of anal fissure consists of pain, marked at the time of bowel movement with occasional bleeding, itching, constipation, anal discharge, the presence of a lump, tightness of the sphincter and tenesmus.

The paper concerns itself with a report of 129 patients, 76 of whom were treated before the introduction of the oil treatment and 53 with the oil injection treatment. The method of injection and the solutions used are described. The end result in both series of cases, although not striking, shows a greater percentage of relief by the use of oil injection than by other treatments. In the cases that were operated on, however, a larger percentage of cures was obtained. Nevertheless, the authors feel that the oil injection treatment is of importance in the treatment of well-established chronic cases, obtaining between 40 and 60 per cent cures in these cases which previously could only be cured by surgery. The avoidance of hospitalization, they maintain, justifies the preliminary use of this method as against operation which could be performed later if the oil injection treatment failed.

Henry H. Lerner, New York, N. Y.

High blood pressure and longevity, and other essays selected from the published writings of David Riesman, M.D., Sc.D., LL.D., Chicago, Philadelphia and Toronto. John C. Winston Co., 1937, 726 pages. Privately printed.

EVERYONE who knows Dr. Riesman either personally or from his writings will be interested in this book, which reveals many of his keen observations and much of his fine philosophy. As would be expected of Dr. Riesman, the essays are written in simple, beautiful English, English that can be read with pleasure. As one would expect also of a wise clinician, Riesman emphasizes that which is so much needed today, namely, the use of the eyes and ears and fingers, the taking of an accurate and adequate history, and the making of a real physical examination. Finally, some cerebration must go into the matter of following clues and deciding what is the most likely lesion to account for the clinical picture as a whole. Riesman knows full well how to use the new methods of diagnosis, but he knows the folly of trying to make diagnoses through them alone, without the help of any cerebration.

Although the title of Riesman's book gives the impression that the articles are mainly on high blood pressure and longevity, actually they deal with all sorts of interesting subjects of decided interest to gastro-enterologists, and in fact, every gastro-enterologist should make a point of reading the article on the taking of a good history. It is packed with valuable information. The article on the recognition of

failing heart by the gastro-enterologist is also very valuable and worth rereading by every clinician in the country. There are a number of delightful essays on the history of medicine and on primitive man. This book would make a fine present for any young man starting out in medicine.

A Bibliography of the Works of Ambroise Paré. By Janet Doe. Premier Chirurgien et Conseiller Du Roy. Chicago, The University of Chicago Press, 1937. Price \$5.00.

THE life and writings of Ambroise Paré, one of the fathers of surgery, one of the most interesting of men, and certainly one of the most interesting of physicians of whom we have record, are well worth studying. Originally a simple barber-surgeon, without learning, he rose by his own efforts to be the ablest surgeon of his time, an able writer, and the companion and friend of kings. For many years his teachings and writings had a tremendous effect on the practice and thought of physicians the world over. To show how far this influence went one need only remark that in the seventeenth century, two hundred years before Perry came to open the ports of the Mikado to foreigners, Paré's great opus was translated into Japanese.

Paré wrote not only on surgery but on anatomy, gout, plague, poisons, obstetrics, monsters, natural history, mummies, pathology, travel and poetry. When writing from his own experience he was forthright and sensible, modern in his scientific outlook, and in advance of the other writers of his time.

Every bibliophile and student of medical history is now indebted to Miss Doe for a beautiful piece of research, during the progress of which she had to ransack the public and private libraries of the world. Every lover of medical books will want a copy of this volume. It is well illustrated, and with all its lucid comments, it constitutes practically a Life of Paré.

A Textbook of Biochemistry. By Roger J. Williams. First Edition, 439 pages, 17 figures, 40 tables. Published by D. Van Nostrand Company, Inc., New York City, 1938.

THE author of this new text indicates as one of his main objectives the development of insight on the part of the student. The selection of material, he states, has been made with this purpose in mind. Whether this objective has been realized to the satisfaction of the majority of teachers and students will only be revealed by the extent to which this text is used in teaching. It seems likely that in many cases a somewhat more detailed presentation will be preferred. The usefulness of this volume for reference purposes, at least, would appear to have been impaired by condensation and elimination. Also certain recent developments which might logically have been included are not discussed.

The author's style is pleasant and readable, and the emphasis and clarity with which the more important aspects of his subject are treated will undoubtedly appeal to many teachers. It may be useful to the clinician who wishes to have a readable review rather than a text for reference on phases of biochemistry which are not of major importance.

Lathan A. Crandall, Jr. Chicago, Illinois.

A simple fact often overlooked...

A truism that is always worthy of attention is the fact that we take too much for granted and know too little about many of the common things of life.

For instance, how many of your patients have given sufficient thought to milk to be impressed by the realization that nature designed cows' milk for the stomach of a calf? How many know that ordinary cows' milk forms large tough curds which have a tendency to irritate an ulcerated stomach?

And isn't it reasonable to assume that patients for whom you prescribe a dietary regimen specifying milk would be interested in learning that Pet Milk, because of the processing of the whole milk from which it is made, forms small flocculent curds which do not have the irritative effect of the large curds of ordinary milk? Would they not be interested in knowing, also, that Pet Milk is sterile, that it is concentrated to double strength, and that when diluted to the consistency of a rich, whole milk it costs less — generally only half as much as ordinary milk?

We should be glad to send you samples and literature.

Non Ulcerative Disease of the Duodenum. By I. Pavel et A. Pauneseo-Podeano. A volume of 204 pages with 57 illustrations. Masson and Co., Editors, Paris.

The history of the duodenum has been so far mainly concerned with the ulcers and its complications, but the authors claim that the other aspects of the duodenum pathology are worthy of an extensive study. For instance, they write that both the pseudo-ulcerative and hemorrhagic types of chronic duodenitis are bound to receive more and more attention in general practice. These conclusions were reached in the course of various researches devoted to some nearly

segment of the digestive tract. The first chapter contains a detailed analysis of the most recent conceptions regarding the duodenal physiology and bacteriology. About the much discussed and varied action of "secretion," normally present in the mucous membrane of the small intestine. They suggest that only the stimulation of liver and pancreas to secretory activity and favorable action on diuresis should be considered as definitely proved. For those interested mostly in the bacteriological point of view, we shall add that not only is the duodenum usually sterile in the normal individual but also that experimental introduction of

germs within its lumen cause positively no damage, because most of the invaders are instantly killed.

This chapter ends by a review of the normal duodenal motility as controlled mostly by X-rays and experimental surgery.

Duodenitis as a clinical entity has been, up to now, according to P. and P.P. only a so-called "residual diagnosis." Every possible affection was brought in mind before duodenitis could be admitted. The patient suffering from duodenitis may be seen with a clinical picture of 1o.—common duodenal ulcer; 2o.—with hemorrhagic symptom; 3o.—with jaundice.

a.—*The common pseudo-ulcerative type.*

Its clinical description so perfectly simulated that of gastric and duodenal ulcer or cholecystitis that roentgenology is primary necessity in arriving at the correct diagnosis. Kirklin has classified in the following order the X-ray findings in duodenitis:

a.—exaggerated irritability of the duodenum, barely allowing visualization on account of the faster transit; b.—reticular aspect of the relief of the mucosa; c.—absence of the typical "niche" of ulcer; d.—absence of gastric retention in non-complicated duodenitis.

Etiology and pathogenesis have shown the frequent association of duodenitis with the gastritis of nervous or heavy drinking patients. Cholecystitis and even appendicitis have also been found in connection with it.

b.—*Hemorrhagic type.*

This monosymptomatic form has also been linked with cholecystitis in 10% of the cases and especially with chronic infection of the ileo-cecal portion. Experimentation has proved, beyond doubts the eagerness shown by the pyloro-duodenal segment in answering by an active and very often hemorrhagic congestion to irritating processes started from any point of the intestinal tract, and from the cecum and appendix, in particular. These facts have been certified in the course of surgical procedures which is also the only way of reaching a correct differential diagnosis.

c.—*Duodenitis with jaundice.*

This type was quite familiar to the medical world of the last century and gradually dropped out of the picture before 1900. The recent introduction of Lyon-Meltzer test in daily clinical work and X-ray advancements have called upon a renewal of the importance of that form of duodenitis which can be thus classified:

1o.—Chronic duodenitis with prolonged jaundice; 2o.—duodenitis in the course of catarrhal jaundice.

Chronic duodenitis with jaundice

TRIAD IN CONSTIPATION

HYPERACIDITY CONSTIPATION HARD FECAL RESIDUE

Haley's M-O—a combination of Phillips' Milk of Magnesia and pure mineral oil—presents antacid, laxative, fecal-softening action in a creamy, homogeneous emulsion.

Haley's M-O attacks all three phases of the constipation problem, provides a complete regulative laxative, gentle in action.

Each tablespoon contains Phillips' Milk of Magnesia 3iii and pure mineral oil 3i.

Dosage

1 to 2 tablespoonfuls, before breakfast and at bedtime.

Supplied in 8-oz., 16-oz., and 32-oz. bottles.

Samples on request.

has the clinical picture of a prolonged catarrhal jaundice coupled with a very satisfactory state of health. A Lyon-Meltzer test, very often impossible on account of the spastic reaction of the duodenum, reveals characteristic cytology and bacteriology—along with positive X-ray findings of congestion and spasticity. Although careful studies have been carried out in many cases, it must still be stated that the disease remains of unknown etiology, pathogenesis and pathology. The Lyon-Meltzer test is the most effective treatment, surgical intervention must, however, be contemplated when jaundice has been lasting over two months.

Duodenitis and catarrhal jaundice. —Different workers in various fields of observation have been very positive about the existence of duodenitis in the course of catarrhal jaundice but radiologic advancement was needed to emphasize these notions. Hatzigano and Hanganotz have X-rayed twenty-four cases of catarrhal jaundice. In twenty cases, they found a disturbed duodenal evacuation, suggestive of atonic stasis. These authors were specially interested in the radiological aspect of the duodenal segment on the course of catarrhal jaundice, because they had been struck by the analogy between the clinical picture of the onset of catarrhal

jaundice and acute duodenal stasis and its secondary intoxication.

The next chapter is devoted to another conquest of roentgenology, diverticulosis of the duodenum. After discussing pathogenesis and pathology, the diversified clinical pictures and complications are studied at length, followed by a careful review of correct roentgenographic technique and proper interpretation of X-ray films. Surgical treatment must be brought forward as soon as dietetics and drugs have failed to relieve pains and prevent complications.

Duodenal stasis. This chapter is a survey of all affections characterized by a delayed emptying of the duodenum. Mechanical causes are expected to be found in most cases; for instance, an unusual flexure, some inside obstacle or a compression from the outside.

P. and P.P. insist on the fact that pathological and clinical findings are directly related to localization as much as to intensity of the stenosis. They draw a complete clinical picture of high intestinal occlusion, including the important blood reactions: high blood urea, acidosis, high alkali reserve, and hyperpolypeptidenia. The severe intoxication encountered in duodenal obstruction is the combined result of excessive loss of fluid, exaggerated toxin production within the walls and lumen of the duodenum and intensified absorption, very unusual in this high portion of the small intestine.

Special mention is made, afterwards, of (a) periduodenitis inflammatory and essential, with its rather deceptive nervous and mental perturbations, (b) compression by the mesenteric pedicle and specific "posture relief" in such a case, (c) and finally, post-operative or rather post-anesthetic duodenal occlusions with their dramatic symptoms and energetic treatment.

Functional stasis is also studied. It is either secondary to spastic duodenitis, or to general hypotonic duodenal reaction. Both ailments may be easily recognized by X-rays.

Belief comments are added, to end the book, about duodenal tumors, peculiar malformations, and parasitology. 57 illustrations, mostly films, very well chosen and expensive, are an important contribution to this up to date survey of duodenal pathology.

Each chapter is a contribution by a former pupil or assistant who under

Choosing a Happy Medium . . .

EXICOL

(Oleic Acid and Bile Salts)

The most recent researches* again emphasize the marked fat-intolerance displayed by patients suffering from gall bladder disease, and the satisfactory therapeutic results on a low fat diet and bile salts. Contrary to recent advocates of high fat therapy, it is pointed out that overstimulation of the gall bladder, produced by such high fat diets is undesirable.

Exicol, containing a small quantity of fatty acid and bile salts, offers a solution to the controversial problem of biliary tract therapy. It is the most rational therapeutic agent in biliary disorders because —

1. It stimulates mild gall bladder contractions due to the fatty acid.
2. Increases bile secretion from 100 to 200% ** due to synergistic action of oleic acid and bile salts.
3. Makes high fat diets unnecessary.
4. Exicol is most effective as an aid in the treatment of chronic cholecystitis, biliary insufficiency and other non-surgical as well as post-surgical biliary tract disorders.

Literature on request.

Put the Patient's System to Work for Him!

Prescribe

VI-SYNERAL

Insufficient vitamin-mineral intake—that's what may be slowing up the patient's recovery! Clinical experience now shows that a great number of ailments are entirely or partially due to vitamin-mineral short rations. Without adequate amounts of these important elements, vital to the health of every cell in the body, your patient cannot make the most of your therapy. Certainly, if the average diet lacks sufficient vitamins and minerals in "good health," how much greater the risk of protective food inadequacy during illness.

Put your patient's system to work for him by prescribing daily doses of Vi-Syneral*, the original multiple vitamin-mineral concentrate. Greater systemic vitality and resistance must assist recuperative power. Your specific medication acts under conditions most favorable for maximum results.

The original scientific formula of Vi-Syneral, pictured above in symbolic form, was developed after 26 years of vitamin-mineral research by Dr. Casimir Funk and Dr. H. E. Dublin.

MINERALS WITH VITAMINS GIVE OPTIMAL RESULTS^{2, 3}

VI-SYNERAL* contains all the definitely recognized vitamins, fortified with eight essential minerals because

...VITAMINS NEED ONE ANOTHER FOR BEST RESULTS

...MINERALS ARE ESSENTIAL TO OPTIMAL VITAMIN EFFECTIVENESS

...VITAMIN AND MINERAL DEFICIENCIES ARE MULTIPLE.

There is a standardized Vi-Syneral potency for every age group. Each box of 50 capsules equals the vitamin and mineral value of hundreds of pounds of fresh vegetables, fruit, milk and other foods.

the instigation of their chief and teacher have been carrying out independent investigation on important problems pertaining to the pathogenesis, dietetic and treatment of nutritional disturbances in man.

These findings have been grouped in this volume with the hope of being of some use to the practitioner.

Much will be found which may on the surface appear only of didactic interest or may appeal to the biochemist, such as the chapters on Polypeptides and amino-acids; the biochemical changes brought about in the large and small bowel, due to variation of intestinal flora. On the other hand, broad views are taken of that complex pathology encountered

in that strange system, which goes to make up, the weakness, the hypersensitiveness and the protection phenomena (organization) of the alimentary tract. It teaches reasons for hypersensitivity and toxicity.

Loeper's personal contribution to this chapter is most inspiring, for it is the outcome of long years of teaching and research which have borne fruits at the bedside as well as in the laboratory.

The role played by histidine in the tissues. The tonic effect of the imidazol compounds reactions. The definite neurovascular changes as due to intestinal disturbances—as an important contribution by Garein.

One may also read with much inter-

est the "Defensive and Protective Factors" of the digestive tract.

A few chapters have been reserved to a study of the Detoxicating action of the liver, to which has been added some interesting research on Deficiency of Vitamin C in the liver. The second part of this volume is limited to a study of deficiency diseases, resulting from alimentary disturbances and chemical changes brought about by gastro-intestinal pathology.

The final chapter gives further treatment to be followed, local and general in digestive insufficiency, as met with in various dyspepsias. This book should answer a purpose i.e. to convey practical knowledge to the practitioner; and if at times there seems to be no effort to develop one principal idea, it appears clearly that in all these contributions are to be found the dominating and inspiring teaching of their chief, who for many years has been a prolific writer, an indefatigable clinician, an investigator of note and who has always called for the full cooperation of the laboratory at the bedside.

A. Cantero.

Abstracts

MINOT, GEORGE R.

Nutritional Deficiency. Ann. Int. Med., Vol. 12, No. 4, pp. 429-442, Oct., 1938.

The modern concept of deficiency disease is given as the failure of consumption or lack of utilization or loss from the body of vitamins, minerals and other nutritional factors essential for health.

The author then discusses the effect of the utilization of energy on the essential nutritional factors and concludes that, in general, the greater the expenditure of energy the more rapid is the depletion of the nutritional factors responsible for deficiency disease.

The following observations substantiate this view: The more rapid development of scurvy and beriberi in individuals engaged in laborious occupations than in those of sedentary habits, other things being equal; the easy development of deficiency disease during infancy and childhood, and during pregnancy and puerperium, when the demand for the essential factors is greatest; the facility of appearance of deficiency syndromes in thyrotoxicosis because of the greatly increased metabolism.

That exhaustion of the supply of nutritional factors in the body is the essential basis of deficiency disease is also shown by the chronic alcoholic who, although deriving many calories

TRI-CALSATE

THE BUFFERED NEUTRAL ANTACID

Neutralizes gastric HCl in the treatment of peptic ulcer, hyperchlorhydria, heartburn, etc., without causing a rebound in acidity.

Maximum (Sippy) dosage can be maintained without harmful systemic effects. Non-toxic . . . Non-irritating. Palatable and economical. Available on Rx in 4½ oz. and 18 oz. bottles.

COD LIVER OIL CONCENTRATE

White's

U.S.P. Minimum Standards.

The widespread professional recognition of White's Cod Liver Oil Concentrate is obvious in the fact that White Laboratories are today one of the world's largest users of cod liver oil. White Laboratories, Inc., Newark, N. J.

For larger dosage. Each capsule provides the vitamin A and D equivalent of not less than 4½ teaspoonsful of cod liver oil.*

CAPSULES

For youngsters and adults. Each candy-like tablet provides the vitamin A and D equivalent of not less than one teaspoonful of cod liver oil.*

TABLETS

For drop dosage to infants. Two drops provide the vitamin A and D equivalent of not less than one teaspoonful of cod liver oil.*

LIQUID

White's Cod Liver Oil Concentrate, Council-Accepted, brings you the therapeutic efficacy of cod liver oil—the vitamins from this time-proved natural source—in dosage forms so palatable and convenient that even finicky patients are not tempted to avoid your prescribed routine.

Most of the published work on the vitamins A and D has been based upon the clinical use of cod liver oil. Thus, the vitamins of cod liver oil come to the physician with an imposing array of credentials—published evidence of efficacy.

CREDENTIALS

The chief fish liver oil used therapeutically, and the only official one, is cod liver oil. Cod liver oil is now widely used as an adjunct in infant feeding. This oil is rich in both vitamins A and D.

FISH LIVER OILS, PREPARATIONS AND CONCENTRATES

Vitamins A and D Preparations

from distilled spirits, develops a deficiency syndrome because he chooses a diet lacking or insufficient in the essential nutritional factors.

Gastro-intestinal tract disorders such as improper reduction of raw materials for absorption, alterations in motor and secretory function, the composition of the intestinal contents, gastro-intestinal diseases, and the influence of effects arising outside the gastro-intestinal tract are considered in the development of deficiency disease.

Defective intermediary metabolism of, and inhibitory influences on the

essential nutritional factors result in deficiency diseases.

Loss from the body of the nutritional essentials such as occur in pregnancy, in kidney disease, in effusions, in serous cavities, in suppuration and drainage of wounds, in hemorrhage, lead to deficiency diseases.

The diagnosis, treatment and prevention of nutritional deficiency diseases is the final topic of discussion before the philosophical concluding remarks.

The reviewers consider this paper

a masterful presentation of the subject which should be read in toto.

JANKELSON, I. R. AND MCCLURE,
CHARLES W.

Observations on the Clinical Status of Gastroscopy. Vol. 219, No. 23, p. 917, 1938.

With a brief, but complete, introduction to the problem of flexible gastroscopy the authors present ten cases in which the value of this new diagnostic procedure is carefully evaluated and shown to be worth while. The demonstration of posterior wall ulcers, ulcers where the X-ray findings were negative, gastrojejunal ulcers, gastric polyps, cases of hemorrhagic gastritis which were mistaken for bleeding ulcers, gastritis itself, as well as the differential diagnosis between ulcer and carcinoma are some of the examples shown.

They make no extravagant claims for the procedure, but merely advance it as a pertinent and valuable adjunct to diagnostic medicine.

The differential diagnosis between cancer and ulcer, which is so difficult even when the specimen is in the hands of the pathologist or surgeon, they admit cannot be made absolutely by the gastroscopist on a single examination.

The authors mentioned two cases in which they made a gastroscopic diagnosis of carcinoma of the stomach and such a lesion was not found at the operation. They also admitted that other errors of observation or interpretation can occur.

Recently, the adoption of the procedure has become more widespread and in the near future will probably be ranked as an office measure. Unfortunately, however, there has to date been no adequate attempt to control the gastroscopic observations by surgical or autopsy material. This is a step that must precede the establishment of the procedure on a sound basis. The ideal combination would be a gastroscope with a flexible biopsy attachment so that specimens of the gastric mucosa could be taken under direct visualization.

Clinical and Hematological Review of Sprue Based on the Study of 150 Cases. Ann. Int. Med., Vol. 12, No. 4, pp. 529-535, Oct., 1938.

The author presents a review of 150 cases of sprue. Only 2 cases were not natives of Puerto Rico. Whites numbered 121, mulattoes 26 and negroes 3. Ages ranged from 9 to 84 years, one-third of whom were below 40 years.

LAROSTIDIN TREATMENT OF PEPTIC ULCER

*Simple • Easy to Administer •
Ambulatory • Prompt Amelioration*

Following are significant excerpts from the conclusions of Mitchell M. Benedict, B.S., M.D., as given in his paper

"Peptic Ulcer and the Larostidin Treatment: A Report on Its Use in One Hundred and Thirty-Two Cases," which

appeared in *The Military Surgeon*, November, 1938: "The parenteral administration of histidine monohydrochloride in 132 cases of gastro-intestinal disorders, 112 of which were peptic ulcer, was followed by rapid remission of clinical symptoms and radiologic evidence of improvement... Regulation of the diet and the mode of living need not be as strict as with other types of treatment... The prompt improvement with the histidine treatment permits the patient to become ambulant early in the treatment... Patients with peptic ulcer tolerate a liberal diet, in the histidine treatment, even during the crisis... The incidence of recurrence was reduced in cases of peptic ulcer receiving the histidine treatment, and all recurrent cases responded satisfactorily to a second treatment... The daily parenteral administration of histidine monohydrochloride has been found the therapy of choice in gastro-intestinal ulcers."

On the lesser curvature a niche the size of a thumbnail, threatening perforation; severe gastritis; extreme hemorrhagic anemia.

After 14 injections of Larostidin: healing; cicatrization of the ulcer; fully able to work.

HOFFMANN-LA ROCHE, INC.

ROCHE PARK, NUTLEY, N. J.

**ADJUNCTIVE
THERAPY**

In Upper Respiratory Tract Infections

Buffer with Kalak

TRADE MARK REG. U.S. PAT. OFF.

● **Palatable
Sparkling
Neutralizing**

AS a valuable aid to treatment in upper respiratory infections physicians are prescribing Kalak because

1. It supplies properly balanced proportions of buffer salts—thereby helping to establish and maintain the salt balance.*
2. It assists dilution and elimination of toxins by promoting diuresis.
3. It offers a valuable adjunct to your analgesic or antipyretic medication.

*In an intensive investigation of respiratory infections, the authors (Pickett-Thomson, Ann. P-T. Res. Lab., p. 605, Dec., '32) found that "There is a decrease in the bicarbonates or reserve bases contained in the blood plasma and the tissues, notably in that of the sodium and calcium salts . . . a lessening of the 'buffer' action of the blood plasma through a decrease in its bicarbonate content."

Kalak supplies the bicarbonates of calcium, sodium and magnesium, as well as the chlorides of sodium and potassium, in a physiologically balanced, palatable, carbonated solution. It is not a laxative.

Kalak Water is available in 24 and 12 oz. bottles. The 12 oz. is particularly suitable for use where an intake of fully carbonated water is desired at each drinking.

KALAK WATER CO. OF NEW YORK, INC.

30 ROCKEFELLER PLAZA
NEW YORK, N. Y.

The author believes that an hereditary factor is present in the etiology of sprue since in 75% of the cases in which a reliable history could be obtained, sprue or pernicious anemia had existed in one of the parents, usually the mother.

The only concept tenable so far, among the many theories advanced, is that of a deficiency disease. The Puerto Rican diet is inadequate in Vitamin A, probably deficient in B, low in calcium and phosphorus, low in fats, high in carbohydrates, the proteins sufficient in quantity but poor in quality, iron content high. The Puerto Rican diet is compared in all these respects with the continental

diet. The author states that diet alone does not explain the whole story.

In this series the blood pressure was low as a rule, almost universal hypochlorhydria or achlorhydria was found, low fasting blood sugar, flat glucose curves (except when glucose was given intravenously), and low metabolic rates (the last studied in only 10 cases). Tetany was never observed.

The most constant laboratory finding is a macrocytic anemia usually hyperchromic, occasionally hypochromic, never microcytic. A megaloblastic type of marrow was found.

The pancreas was normal in 18 of

the 20 cases autopsied. No osteoporosis or osteomalacia was found.

The disease is regarded primarily as one of the hemopoietic system and not of the gastro-intestinal tract.

The disease responded very well to treatment with concentrated liver extract despite its low Vitamin B content.

The yearly death rate from sprue in Puerto Rico is 65 per million inhabitants.

B. B. Vincent Lyon and
John De Carlo, Philadelphia.

WRIGHT, IRVIN S.

Cevitamic Acid (Ascorbic Acid; Crystalline Vitamin C); a Critical Analysis of its Use in Clinical Medicine. Ann. Int. Med., Vol. 12, No. 4, pp. 516-528, Oct., 1938.

The author presents a method of approach for the determination of the degree of saturation or deficiency of Vitamin C in the body for clinical appraisal.

Three tests are suggested: First, a single determination of cevitamic acid in blood plasma, using the macro method of Farmer and Abt. Second, urinary saturation test which consists in the intravenous administration of 1000 mg. of cevitamic acid and analyzing the urinary excretion of cevitamic acid for the following 5 hours, because the author and his co-workers found that 80% of the 24 hour excretion occurred in the first 5 hours. With kidney disease and nitrogenous retention, the author suggests parallel and blood and urinary determinations to clarify the picture. Third, the capillary fragility test, for which the author suggests the use of the blood pressure apparatus. The sources of errors and fallacies for all of these tests are given.

The symptomatology of scurvy is given and the author stresses the prevalence of the disorder in its pre-clinical forms, in all economic classes.

The curative and maintaining oral dose of cevitamic acid is given as from 30 to 50 mg. per day, but varies greatly in different individuals. Intravenous administration should be used when high oral dosage fails. Large doses of lemon and other citrus fruits have cured cases resistant to cevitamic acid even when given intravenously.

Diseases, other than scurvy, benefited by the administration of cevitamic acid are mentioned.

B. B. Vincent Lyon and
John De Carlo, Philadelphia.

ROBERTSON, ELIZABETH C.

Low Mineral Diets and Intestinal Stasis. University of Toronto Studies. Pathological Series No. 9, 76 pp., 1938.

Low mineral diets will induce a

NO patient is more grateful than the chronic sufferer from arthritis or rheumatism, for medication that affords quick relief and which at the same time is safe and palatable.

These factors combined in Salici-Vess have made it, in a very short time, a preferred prescription to afford quick relief from pain and muscle spasm.

The formula of Salici-Vess combines Sodium Salicylate 7½ grs., Sodium Iodide 1 gr., Citric Acid 17 grs. and Sodium Bicarbonate 25 grs. in an effervescent tablet. When dissolved, each tablet gives approximately 4 grains free Sodium Bicarbonate and approximately 24 grains Sodium Citrate.

Other interesting Effervescent Products now available are: Aspir-Vess (aspirin with alkali buffers), and Alka-Vess (for safe alkalization).

Intractable?

Irritable Colon and Functional Diarrhea • Chronic "Toxic Vertigo" • Mucous Colitis • Chronic Headaches from Chronic Constipation or Colon Distress

THESE symptoms typify conditions previously regarded as intractable . . . but now responding favorably to a "comprehensive plan of therapy" including use of Soricin Tablets alone or in combination with B. Coli Vaccine-Detoxified with Soricin.

This method of treatment was developed and refined in extensive clinical

investigation over a period of nine years. It is now being used by many gastro-enterologists with gratifying results.

Write for your copy of booklet *The Therapeutic Use of Soricin with Colon Bacillus Vaccine Therapy*, which completely describes the "comprehensive plan of therapy."

SORICIN

A special brand of the detoxifying agent sodium ricinoleate, available in 5 gr. tablets and 5 gr. and 10 gr. capsules.

B. Coli Vaccine-Detoxified with Soricin

B. Coli Vaccine-Detoxified (Mettell) is prepared from selected strains of B. coli communis (*Escherichia coli*) and B. coli communior (*Escherichia communior*) mixed in equal proportions

and detoxified with Soricin (sodium ricinoleate).

For convenience in graduating dosage, a series of dilutions is available ranging from 5 thousand to 1000 million killed organisms per cc.

Established 1923
Cincinnati, U. S. A.

hypotonic condition of the colon and consequent constipation. To study this phenomenon, diets which were low in K and Ca were fed to test groups of rats; control groups, consisting of litter mates, were kept on adequate diets. As indicators of stasis, carmine and BaSO₄ both were employed. For the experimental groups, the average excretion times for these substances were 13 and 10 days respectively; for the control groups they were 5 and 4 days respectively. Subsequent feeding of an adequate diet relieved the stasis in all cases. Ca-low diets gave more marked effects than K-low diets; in fact the

effect of K is manifest only when the total mineral intake is kept low. None of these constipational effects were prevented by the presence of roughage (powdered filter paper) or by an increase in the dietary intake of the Vitamin B complex. Such low mineral diets induce a condition of antonomic imbalance.

Similar studies were carried out on a group of 19 hospitalized children. The diets were entirely adequate except with respect to Ca and K. Of these 19 children, 74% became constipated while on the diet. When given a Ba meal, 33% of them retained the Ba in the appendix for as long as

4-21 days. On normal hospital diets, or when the previous diets were supplemented with KCl and Ca-lactate, Ba retention in the appendix never persisted for longer than 24 hours.

Franklin Hollander, New York.

HUBENY, MAXIMILIAN J. AND POLLACK, SIMON.

Diverticulosis of the Small Intestine. Am. J. of Roent. and Rad. Ther., Vol. 40, No. 5, p. 639, 1938.

The authors report an interesting case of diverticulosis of the small intestine, the rarity of which is obvious when we find but thirty cases reported in the literature since 1934. Of these, eight were incidental findings at post-mortem examination.

The theory of locus minoris resistentiae as the etiology is probably the best accepted of all those advanced. The two important factors are the presence of a weak site in the bowel wall at a vascular perforation plus a pulsion force as a result of spasm. The pathology consists of small, multiple, thin walled sacs along the mesenteric border, usually in the upper jejunum. Most cases are multiple and the diverticula themselves may become bifid.

The complaints which may bring the patient to the physician for medical aid are inflammation, hemorrhage, perforation, intestinal obstruction, enterolith formation, and torsion. The symptom complex varies from vague epigastric distress after meals with fullness and eructations, to the clinical picture of peritonitis or obstruction. The diagnosis can only be made by X-ray which shows small round barium filled shadows in films of the small bowel.

BROWN, WILLIAM REDMAN, HANSEN, ARILD EDSTERN, BURR, GEORGE OSWALD AND MCQUARRIE, IRVINE.

"The Effects of Prolonged Use of Extremely Low-Fat Diet on an Adult Human Subject." Jour. of Nutrition, Vol. 16, p. 511, 1933.

Brown, Hansen, Burr and McQuarrie report an interesting experiment carried out to determine whether the prolonged use of a low-fat diet would exert a harmful affect upon normal human subjects. This experiment was inspired by the results obtained on rats when the young animals placed on a diet low in fat showed retardation or cessation of growth, severe dandruff, scaliness of the feet and tail, hematuria, and premature death. One of the authors acted as subject and lived for some months on a diet limited to sucrose, potato starch, baking powder, sodium chloride, ferric citrate, viosterol, carotene, orange juice, citric acid, anise oil, liquid

Petrolagar Plain

AN ADJUNCT TO THE RESTRICTED DIET

During a period of restricted diet, bowel regularity may be maintained with the aid of Petrolagar Plain. As an adjunct to the diet, Petrolagar induces a soft, well-formed stool and encourages a regular habit time for bowel movement.

If the case is severe, Petrolagar

Plain may be given in alternate doses with Petrolagar with Cascara until proper elimination is established. Then Petrolagar Plain alone will assist in maintaining a regular, comfortable movement.

There are five types of Petrolagar to suit the individual case.

Petrolagar—Liquid petrolatum in an emulsion with 0.5 Gm. of Cascara in each 100 cc. of the liquid.

Petrolagar

Petrolagar Laboratories Inc. • 8134 McCormick Boulevard • Chicago, Illinois

KONSYL

A Rational Regime in the Treatment of Constipation

As you know, the undesirable ingredients in most constipation-correcting products are:

1. IRRITATING DRUGS which require increasingly larger doses, and often result in symptoms more unpleasant than those of constipation.
2. COARSE ROUGHAGE which irritates the gastrointestinal tract.
3. MINERAL OILS which have a tendency to interfere with digestion and absorption, and which often leak in an embarrassing manner.

KONSYL, however, has none of these undesirable qualities. It is the original non-habit forming concentrated vegetable muciloid made from *Plantago Ovata* which prevents constipation by absorbing water and swelling into a soft, bland "jelly" bulk which lubricates the bowels without irritation or leakage.

Write for clinical test sample and literature.

Also manufacturers of L. A. FORMULA containing Lactose, Dextrin and *Plantago Ovata* Concentrate. AJ 2-39

A Teaspoonful makes a Tumblerful of "Jelly"

BURTON PARSONS & COMPANY

Serving Physicians since 1885
Washington, D.C.

For bland diet therapy, especially ULCER cases ... PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastrointestinal disorders is a deficient diet. Pablum is rich in a wide variety of the accessory food factors and can be fed over long periods of time without danger of gastrointestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than does farina and is an excellent source of vitamins B₁ and G. Also rich in calcium and phosphorus.

Requires no cooking. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Can also be used in a variety of appetizing dishes to enhance their vitamin and mineral values. Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal (farina), oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, reduced iron and sodium chloride.

Samples and literature sent on request of physicians.

petrolatum and milk freed of its fat. As a result of this diet carried out for six months, no harmful symptoms developed. A slight degree of hypertension disappeared and migraine disappeared. The respiratory quotient rose to more than unity after meals. The iodine number of the total fatty acids of the serum fell from 123 to 93. Also the linoleic acid of the serum was reduced. It cannot be assumed that the human subject could live indefinitely on such a diet devoid of the unsaturated fatty acids.

Howard F. Root, Boston.

CRAFT, CHARLES C.

The Effect of Ephedrine on Pancreatic Secretion; a Method of Management of Patients Having a Pancreatic Fistula. Surgery, 4, 64-73, 1938.

In all, six dogs were provided with complete pancreatoduodenal fistulae; subsequently, these animals were given subcutaneous injections of 10 mg. of ephedrine every two hours. Of nine such experiments, eight yielded decided diminutions in volume of pancreatic juice secreted. Inhibition of secretion reached its maximum during the first hour following injection and had usually disappeared by the end of the second hour. Since there were no toxic manifestations, it is suggested that similar injections of ephedrine may prove helpful in the management of clinical cases of pancreatic fistula. By reducing the flow of pancreatic juice, it may become possible to minimize or prevent erosion by this secretion of the outer abdominal wall surrounding the stoma of the fistula. Another possible method of preventing such erosion is by the use of a dressing made of dry silica gel, which was found effective in treating dogs with leaking fistulae.

cretion was also evoked. The active principle of pyloric extract is soluble in 80% methyl and ethyl alcohols and dilute acetone, and is precipitated from aqueous solutions by 10 to 30% NaCl, depending on the pH.

M. H. F. Friedman, Detroit.

MYERS, G. NORMAN AND DAVIDSON, S. WHATELY.

An Investigation of the Effects of Certain Substitutes for Morphine and Heroine Upon the Passage of Food Along the Alimentary Tract of the Human Subject. Jour. Hygiene, 38, 432-45, 1938.

The effects on human subjects of a number of drugs—dilaudid, diordid, eukodol—were compared with those of morphine and heroine. Dilaudid and eukodol are very similar to morphine in their effects; tonus of both pyloric and ileocecal sphincters was increased, as a result of which there was a marked delay in passage of food from the stomach into the duodenum and from the small intestine into the cecum. Diordid, however, exerted a much weaker action than morphine or heroine in regard to these sphincters.

Franklin Hollander, New York.

An Aid To Normal Bowel Function KARAJEL

KARAJEL prepared from Karaya Gum is processed to provide prolonged hydration in the intestinal tract.

KARAJEL produces a moisture retaining jell-like bulk, smooth and non-irritating. Encourages normal peristalsis and develops easily expelled, well-formed stools.

Patients with constipation of all types, who do not have organic diseases, can resort to it for longer periods of time.

There are four types of KARAJEL: KARAJEL Plain; with Belladonna; with Belladonna and Phenobarbital and with Vitamin B.

Presented as a prescription item to the medical profession only.

Prompt symptomatic relief in DIARRHEA

• KAO-LACTOS B is a combination of three ingredients therapeutically indicated for the relief and correction of many conditions associated with diarrhea:—

Crookes colloidal kaolin adsorbs toxic material, allays irritation of intestinal mucosa and is an effective palliative measure in diarrhea . . . Lactose, a valuable nutrient, favors the development of a healthy intestinal flora while the Vitamin B complex furnishes a supply of necessary vitamin in those states where intestinal absorption has been impaired.

KAO-LACTOS B is supplied in powder form in 4 oz. bottles and 1 lb. tins . . . Dose: 1 to 2 teaspoonfuls in water 3 times a day, before meals.

CREAM OF WHEAT

*now provides these essential Minerals
... and Natural Vitamin B₁*

WITHOUT increase in its reasonable price, Cream of Wheat, now enriched with wheat germ, tricalcium phosphate, and ferric orthophosphate, provides appreciable quantities of iron, calcium, phosphorus, and vitamin B complex. It complements admirably the dietaries of infants and children, contributing to the normal requirements of calcium and phosphorus, and aiding in the prevention of nutritional anemia.

Iron . . . Highly Available

Each 100 Gm. of Cream of Wheat now provide 42.6 mg. of iron in the form of readily absorbed and utilized ferric orthophosphate. The addition of this enriched Cream of Wheat to the diet of infants and children, in the usual quantity, aids in the prevention of secondary anemia and in hemoglobin regeneration if anemia is present.

Calcium and Phosphorus

Through its added tricalcium phosphate, Cream of Wheat now exhibits 593 mg. of calcium and 505.5 mg. of phosphorus in each 100 Gm. These nutritionally needed elements, as provided in Cream of Wheat, readily enter into the mineral metabolic processes of the growing infant and child. Together with the usually consumed milk, they more than meet the calcium and phosphorus requirements.

Vitamin B₁ . . . Natural

Repeated biologic assay reveals that the vitamin B complex of the wheat germ added to Cream of Wheat provides approximately 60 international units of natural vitamin B₁ per 100 Gm. of cereal. This important vitamin is

needed for proper growth, contributes to normal gastro-intestinal function and to a good, healthy appetite.

Completely Cooked to Excellent Digestibility . . . in 5 Minutes

By means of a unique processing procedure, Cream of Wheat is now cooked to excellent digestibility in five minutes. It may be safely fed to infants and children after this short period of cooking, with complete assurance that its nutritional substances are made available.

Enriched in Palatable Taste

The new Cream of Wheat, with its nut-like, wheaty flavor, tempts the palate even more than the familiar older preparation. Infants, children, and adults take it readily; even daily consumption over long periods does not cloy the appetite. In appearance it is creamier, more inviting.

Advantageous for Every Cereal Purpose

Now more than ever Cream of Wheat fills every cereal need. It is an ideal first solid food for infants; a desirable component in the dietaries of growing children; an excellent bland yet nutritious food in gastro-intestinal involvements and during convalescence, and of established value in the therapeutic regimen of the pylorospasm of infants.

The Takata-Ara Reaction. II. Mechanism—With Special Reference to the Influence of the Ammonia Blood Level. The Jour. of Laboratory and Clinical Medicine, Vol. 23, No. 9, 894-903, June, 1938.

The authors studied the relation between the ammonia content of the blood serum and the Takata-Ara reaction. They found that there was a definite relation between these 2 tests. It was, however, obvious that most cases with a positive Takata-Ara reaction had an alternation of the albumin-globulin ratio. Chasnoff and Solomon believe that the altered albumin-globulin ratio, although not the sole factor, is probably the most important one in the mechanism of the Takata-Ara reaction.

Franz J. Lust.

MARSHALL, WILLIAM A.

Pancreatic Lithiasis, with a Case Report and Autopsy Findings. Radiology, Vol. 31, No. 5, p. 562-566, Nov., 1938.

A case of pancreatic lithiasis is described. Very good roentgenograms show the site of the concretions. The author emphasizes the fact that a plain radiogram of the abdomen is important to arrive at a diagnosis. The routine gastro-intestinal study, with the use of barium, may hide the stones. Early diagnosis is of extreme importance as timely surgery may cure the patient by preventing atrophy and destruction of the glandular tissue. The reported case was complicated by a carcinoma of the body of the pancreas.

Franz J. Lust, New York.

The Wolf-Schindler Flexible GASTROSCOPE

This instrument presents no element of risk. It is as easily introduced as a stomach pump or rubber tube, thus eliminating danger and discomfort to the patient. It may be turned in any direction and remains flexible during observation. Stomach linings and pylorus appear in natural color with unsurpassed detail within a field of view comprising 50 or 90 degrees. Price \$650. Special tube for local anesthesia \$10. Spare bulbs with rubber finger \$6.50 each, f.o.b. New York.

Science calls the common banana "Musa Sapientum," which means Fruit of the Wise Men. According to ancient legend, the sages of India reposed in the shade of the banana plant and refreshed themselves with its luscious fruit.

INTERESTING BANANA FACTS

THE ripe banana contains about 20% sugars with nearly 5% other solids consisting of protein, fat, pectins, minerals, vitamins and small amounts of starch and fiber. Its semi-solid texture must hence be attributed to the way in which moisture, sugars and the other constituents are held in a delicate meshwork of cellulose and pectin substances, and *not* to low moisture or high fat content. The sugars present are sucrose, levulose and dextrose. The two simple sugars account for about 40% of the total sugars.

The key to the varied usefulness of the banana is to be found in its composition. Special points stand out as qualifying it for inclusion in special types of diets. These are summarized in outline form below:

PROPERTIES OF RIPE BANANA PULP	MAKE IT OF VALUE IN
Readily assimilated sugars (along with vitamins, minerals and fiber)....	.. Infant Feeding
Caloric value (along with vitamins and minerals)....	.. Malnutrition
Satiety value and low fat (along with vitamins and minerals) Reducing Diets
Alkaline residue Combating Acidity
Vitamin content Preventing Deficiency Diseases
Soft texture and blandness (with carbohydrates, vitamins, minerals, pectin and fiber).....	{ Intestinal Disturbances Normalizing Colonic Function Convalescent Diets

AS ONE PHYSICIAN TO ANOTHER... WHAT IS THE CAUSE OF CONSTIPATION?

OBVIOUSLY, there is no single cause. Each case must be judged on its own merits. Anatomical differences, variations in diet and habit and specific pathological entities all enter into the cause. However, it is safe to say that faulty habit plays a role in the great majority of cases, and that loss of neuro-muscular tone is a very common secondary factor.

To make habit training easier, a bland, pure mineral oil is important. To increase tons of debilitated intestinal musculature and nervous system caused by Vitamin B-1 deficiency, pure crystalline Vitamin B-1 has been found to be of great value.

In *Vita Nujol*, these two important aids in the relief of constipation have been combined.

Vita Nujol is a smooth, pleasant-tasting emulsion of pure mineral oil with pure crystalline Vitamin B-1 added in such quantity that the suggested average dosage is the average adult maintenance dose of that important food factor (400 International Units).

Vita Nujol has a place in the treatment of the majority of constipation cases, and also in the gastro-intestinal syndromes of chronic alcoholism and many other pathological states associated with Vitamin B-1 deficiency.

Vita Nujol has been thoroughly tested and proven in laboratory and clinic.

A postal card will bring you free samples and descriptive literature. Stanco Inc., 1 Park Avenue, New York, New York.

General Index for Volume Five

Abscess, ischio-anal	644	Aluminum hydroxide	97, 164, 486, 652, 792
Absorption from G.I. tract	164	Amebiasis	153
gastric	657	Ammonium chloride	615
intestinal	690	Ampulla-duodenal	20
of protein	345	Anacidity	4
Acetylbetamethylcholine	224	Analysis, gastric	739
Acetylcholine	224	Anemia, and G.I. tract	402
Achlorhydria, attempts to produce	30	idiopathic hypochromic	270
Achylia	405, 617, 774	Anorexia	814
Acid, ascorbic	336, 493	Antiseptics	418
cholanic	613	Antuitrin-S	24
choleic	613	Anus, contracted	162
hydrochloric	367	imperforate	263
Acidity, gastric	86, 104, 292, 364, 373, 777	Appendectomy	652
Acidosis	92	Appendicitis	379, 304, 450, 804
Acids, keto bile	291	acute	400
Adenoma of colon	161	Appetite	436
Agar	97	Arteriosclerosis	92
Alcoholism	405	Ascariasis	618
Alkalosis	461	Ascorbic acid	406
Allergy	640	Aspirin	615
food	730	Atherosclerosis	326

Athletes, diet of	704	Dechacid	615
Avitaminosis	714	Decholin	615
Azochloramid	557	Defense mechanism	428
		Deficiency, vitamin A and C	40
Bacillus coli	176	Deformity, napkin-ring	159
paratyphosus B	176	Diabetes	58, 127, 696
Welchii	316	and ulcer	663
Bacterium, necrophorum	85	in children	342
Bargen's organism	281	Diagnosis by duodenal drainage	1
Beet juice	97	of colitis	242
Benzedrine sulphate	446	Diarrhea	50, 155
Bile, dried	650	and vitamin B	636
duct, common	62	epidemic	278
flow of	20	Diastase, of blood	184
pH of	288	Diet, balanced	437
salt therapy	348, 377	high protein	743
tract, in ulcer	99	hydrophilic colloidal	96
volume of	613	in cholecystitis	349
Blood, regeneration	125	in colitis	243
serum	231	in colostomy	382
Bowel consciousness	9	in defense	428
Brain injury, with ulcer	113	in diabetes	88
Buffer salts	311	of ancient man	191
		Disease, hepatic	184
Cactus juice	97	Diverticuli of bowel	454
Calcium and vitamin C	408	Diverticulitis	57, 132, 263, 654
deficiency	394	Diverticulum, esophageal	57
gluconate	616, 684	Drainage, duodenal	1
metabolism	676	Ducts, biliary	525
Calomel	615	Duodenum, enzymes of	464
Cancer	448	Dyes	30
of colon	158, 566, 632	Dysentery, amebic	153, 264, 398
of G.I. tract	714	bacillary	159, 562, 684
of jejunum	650		
of liver	142	Edema, menstrual	263
of pancreas	683	Emergencies, G.I.	712
of rectum	52	Emmenin	30
of stomach	549	Endocrines	587
primary	420	Enema	809
rectal	208, 342, 456, 749	Enema tip	791
Carbonate in urine	461	Enteritis	274
Carcinoma of ileum	54	regional	648
of rectum	55	segmental	456
Catarrh, of bile duct	101	Enzymes, duodenal	464
Cerebrum	20	Eosin	30
Charcoal	383	Epilepsy	295, 390
Cholangiograms	378	Ergamine acid phosphate	30
Cholecystitis	72, 348, 379	Esophagitis, peptic	175
surgery in	332	Esophagus, burns of	327
treatment	694	obstruction of	336
ulcerative	746		
Cholecystography	1, 583, 785	Fat, in test meal	18
Cholesterol	597	Feeding, continuous drop	39
in milk	15	Ferments	628
Cinchophen ulcers	534	Fever, in ulcer	779
Cirrhosis, Laennec's	336	Filters, color	38
of the liver	60	Fissure, anal	52
portal	414	Fistula, of ileum	398
Cobalt acetate	30	Flora, bacterial	428
Cod liver oil	208, 426	Food allergy	730
Colitis	554	idiosyncrasy	394
catarrhal	297	sensitivity	801
chronic ulcerative	361	Function of gall bladder	568
in children	646		
oxygen in	84	Galactose	597
regional	55, 62	Gall bladder disease	441, 576
ulcerative	156, 239, 259, 426, 562, 652	emptying	583
Colon, cancer of	566	function	568
carcinoma of	380	infection	571
disorders of	712	physiology	687
obstruction of	380	rupture	452
perforation of	66	surgery	667
Colostomy, permanent	382	Gall stone	288, 411, 768
Congo-Red	30	Gastrectomy	57
Constipation	170, 702	for ulcer	497
Cyst, of omentum	252	Gastric absorption	657
Cystic duct	576	analysis	644, 739, 786

drainage	661	Lipocalc	142, 607
emptying	523, 770	Liver, atrophy of	72
motility	18	cancer of	330
secretion	224, 467, 617, 714, 760, 762, 764	Liver damage	130
Gastritis	57, 353, 386, 528	disease	758
alcoholic	98	effect of arsenates	328
atrophic	355, 477	fatty infiltration	263, 439
catarrhal	354, 475	fatty metamorphosis	607
chronic	472	function	757
hypertrophic	355, 478	Lymphogranuloma	554
ulcerative	476	inguinale	64
Gastro-intestinal disease and vitamins	405	Magnesium trisilicate	422
Gastrojejunostomy	52	Malfunction, chronic G.I.	246
Gastro pump	360	Mann-Williamson operation	373
Gastriorrhagia	115	Meal, gastric	18
Gastroscopy	134, 218, 334, 472, 501, 745	test	721
Gelatin	97	Mecholyl	687, 736
Germicides	418	Melanosis coli	693
Glucose tolerance	4, 597	proctocoli	681
Glycosuria	57	Methemoglobin	283
Goiter and ulcer	266	Methylcholine	687
exophthalmic	268	Methylene Blue	30
Gout	53	Migraine	189, 295
Gum, karaya	315	Milk, acidophilus	170
HCl, formation of	523	cholesterol in	15
Healing, experimental ulcer	24	vitamin C in	251
Heart disease	338	Motility, gastric	18, 814
Hematemesis	115	Mucara	319
Hemorrhage, from ulcer	66	Mucin	97
gastric	98, 634	Mucosa, oral	418
rectal	328	Mucous	369
scorbutic	42	Mycosis	674
Heterophyidiasis	340	Negro, diseases of	298
Histamine	109, 753	Nephritis, dietary	68
Histidine	117	Nesidioblastoma	212
Hormone, estrogenic	292	Neurinoma	774
pituitary-like	777	Neuritis	456
Hunger	436, 718	Neutral red	617
Hypercholesteremia	532	Nicotine poisoning	55
Hyperinsulinism	268, 336	Nicotinic acid	807
Hypertension, portal	357	Nutrition after operation	72
Hypoglycemia	88, 470	normal	204
Hypothyroidism	295	Obstruction, intestinal	379, 396, 654
Ileitis, recurrent	212	pyloric	785
regional	54, 55, 132, 441	Orange juice	86
terminal	313	Organism of Bagen	281
Ileum, absence of	336	Ox-bile, in treatment	288
Ileus	654	Oxygen, introduced in colon	84
Indians, nutrition of	432	Pain	701
Indigo carmine	30	in cancer	732
Insufficiency, hepatic	126	Pancreatitis	138
Insulin	644, 753	experimental	423
protamine	88	Papilla of Vater	534
regular	89	Parasites, intestinal	638
Intestinal absorption	690	Pellagra	718, 807
Intubation of intestine	452	secondary	112
Intussusception	322, 654	Pepsin	30, 368, 624, 661
Iron	540, 700	Peptic ulcer	58, 60
Irrigation	384	treatment	422
Jaundice	138, 270, 276, 597, 636	treatment of individual	12
bleeding in	334	Perforation, acute	377
spontaneous	640	Peritonitis	380, 804
vitamin K	590	gonorrheal	818
Jells, silica	97	Pernicious anemia	146, 263, 102, 700
Kaolin	684	Personality of patient	13
Karaya gum	315	Phenolphthalein	223, 297, 627
Ketochol	615	Phenol red	657
Larostidin	30	Phosphatase	597
Laxative gum	315	Photography, infra-red	414
Laxatives	9	Phytobezoar	444, 745
Lesions, follicular	40	Pilocarpine	123
Lipase, serum	423	Pitressin	30, 642
Lipids, metabolism of	338	Pituitary extract	450, 638
		gland	393

Pituitrin	33	for G.I. lesions	221
Poison, shell-fish	55	meal	721
Polypi, of colon	566	Theelin	30
Polyposis	160	Thiamin	406
Porphyrimemia	49	Thirst	436
Potassium citrate	30	Toluidine Blue	30
Proctitis	340	Toxemia, intestinal	390
Prostigmine	224	Transfusions	244
Protein diet	743	Trasentin	121
in experimental ulcer	36	Treatment, by diet	326
in test meal	18	cholecystitis	694
undigested	345	gastritis	472
Psychiatry	482	of foods	627
Psycho-analysis	14	peptic ulcer	422, 454
Psychology, of negro	300	ulcerative colitis	426
Pump, gastro	360	Tube, duodenal	165, 381
Purpura, gastric	796	gastro-duodenal, new	77
Pyloric obstruction	785	stomach	165
Reactions, allergic	437	Tuberculosis, colonic	159
Takata	231	intestinal	442
Rectum	774	Ulcer, aluminum hydroxide in	486
anomalies of	400	and diabetes	663
impalement of	640	ascorbic acid in	493
in diarrhea	155	bleeding	378, 646
prolapse of	380, 393	drop feeding in	39
stenosis of	330	duodenal	99, 214, 257
Reflex, carotid sinus	444	experimental	24, 36, 104
Reflexes, conditioned	20	fever in	779
"Relief," gastric	81	healing of	501
Resection of pancreas	53	hemorrhage from	125
Riboflavin	406	histidine in	648
Rotation, intestinal	217	in syphilis	538
Saliva	365	jejunal	792
Secretagogue effect of food	468	of esophagus	725
Secretion, gastric	107, 373, 467, 736, 753	of gall bladder	173
Secretagogue	721	pain in	260
Selenium	53	peptic	113, 540, 816
Sera	244	causes of	751
Shock	129, 202	protein diet in	3
Sigmoidoscopy, color filters in	38	"relief in"	81
Silver nitrate	20	rupture of	632
Sodium phosphate, monobasic	30	surgery of	454
selenite	30	treatment in	389
thiosulphate	30	Ulceration of G.I. tract	627
Soy beans	177	Vaccines	244
Splenomegaly	642	Vaginitis	536
Sphincter of Oddi	411	Vagotomy in ulcer	497
Spirochetes	700	Vagus nerve	772
Sprue	406	Varix, esophageal	357
non-tropical	254	Vitamin B complex	246
Stenosis, pyloric	278	Vitamin B ₁ , overdosage	680
Stomach, cancer	549	Vitamin C	251, 408, 650
function of	817	and calcium	676
mycotic infection	674	in ulcer	538
pouch	766	Vitamin K	590
Stone	528	Vitamins	405, 756
Stones, common duct	276	Vomiting, functional	136
Streptococci, colonic	281	Water balance	49
Streptococcus, faecalis	283	X-ray "relief"	81
mitis	283	X-ray studies, ulcer	501
salivarius	283	X-ray technique	768
Sulphanilamide	615		
Surgery, in colitis	245		
in ileitis	313		
Takata reaction	231		
Test, Anson and Mirsky	661
